Gill *et al.* performed a multi-institutional review of 185 patients who underwent a laparoscopic nephrectomy, 153 of which were for benign disease [137]. Complications were threefold higher among patients undergoing radical (34%) versus a simple nephrectomy (12%). Access-related complications occurred in 2%, including one abdominal wall lesion, one trocar injury to a hydronephrotic kidney, and one hernia at a port site. Intraoperative complications included an ipsilateral pneumothorax attributed to transpleural insertion of a secondary port requiring a chest tube. Another patient suffered a splenic laceration which appeared to resolve with direct pressure, but ultimately led to a postoperative bleed and need for an open splenectomy. Other authors have successfully utilized a fibrin sealant to achieve adequate hemostasis laparoscopically when splenic laceration occurs [138]. Three patients (2%) developed a postoperative ileus, two (1.3%) cardiovascular complications, two (1.3%) urinary retention, and two (1.3%) neurologic complications. The incidence of elective conversion during laparoscopic simple nephrectomy was 3.3% with no emergent conversions.

Dissection and securing of the hilar vessels is the step related to the greatest number of "crash" conversions due to uncontrollable hemorrhage. In the series by Siqueira *et al.* all five emergency conversions, three during live donor and two during radical laparoscopic nephrectomy, occurred while dissecting and/or securing the hilar vessels or their branches. Two of these episodes resulted from a misfired or misplaced Endo-GIA stapler. Similarly, Gill *et al.*'s series reported emergency conversions for three vascular injuries, all within the laparoscopic radical nephrectomy group and none in the simple nephrectomy group [137]. One of these vascular injuries occurred as a result of a malfunction of the Endo-GIA stapler. Malfunctions during securing the hilar vessels with the Endo-GIA stapler have been reported with an incidence of 1.7%, with 50% resulting

from misplacement over previously placed clips [90]. As a result of such occurrences, several authors advocate use of devices such as the LigaSure (Valley Labs, Boulder, CO, USA) [90], bipolar coagulation [139], or the Harmonic scalpel to secure the branches of the main renal vein to prevent incorporation of clips within the Endo-GIA stapler.

In a review of 2407 laparoscopic cases in urology, Fahlenkamp *et al.* demonstrated a 0.8% incidence of adjacent organ perforation [131]. They also noted a 3:1 ratio for the incidence of visceral injury during the transperitoneal versus the retroperitoneal approach, respectively [131]. In Siqueria *et al.*'s series of 213 laparoscopic nephrectomies, visceral injuries included two (0.9%) liver and one (0.5%) splenic injury [63]. Bowel injury occurred in two patients (0.9%), which is similar to the 0.8% incidence of bowel complications reported by Bishoff *et al.* in a group of 915 patients who underwent assorted laparoscopic urologic procedures [140]. Unfortunately, 70% of laparoscopic bowel injuries are not recognized intraoperatively and present with an unusual constellation of signs and symptoms unique to laparoscopic-associated perforations. These include disproportionate single trocar site pain, abdominal distention, diarrhea, and leukopenia followed rapidly by cardiopulmonary collapse [140].

Heminephrectomy

Complete duplication of the collecting system is found in one of 125 individuals [3]. The primary indications for surgical intervention include an ectopic ureter associated with a poorly functioning dysplastic upper pole moiety or an upper pole moiety with chronic obstruction and resultant poor function. Destruction and hydronephrosis of the lower pole system can also result from reflux nephropathy or a UPJO [5]. Recurrent infections, flank or abdominal pain, and incontinence may also be present [4]. Surgical intervention includes removal of the diseased moiety as well as all or a portion of the associated ureter. The laparoscopic approach to upper pole heminephrectomy was first described by Jordan *et al.* in 1993 [141]. This has since become an increasingly popular technique for the treatment of patients with this condition. Both the transperitoneal and retroperitoneal approaches have been described [5, 141–144], although most authors seem to favor the transperitoneal exposure due to the more familiar orientation of the hilum and improved working space [142].

Instrumentation

The instrumentation required is listed in Table 81.6.

Table 81.6 Instrumentation for heminephrectomy (University of Wisconsin, Madison).

Standard cystoscopic pan (*optional*)
0.035-inch floppy-tipped wire (*optional*)
6F open-ended catheter (*optional*)
Ampule of methylene blue (*optional*)
Four nonbladed trocars: two 5 mm and two 10/12 mm (with reducers)
Two 10-mm laparoscopes: one 0° and one 30°
Two 5-mm laparoscopes: one 0° and one 30° (available in the room)
One 14G Veress needle
One 10/12-mm blunt-tipped cannula (available in the room)
One trocar-mounted balloon dilation device (Origin Medsystems, Santa Clara, CA, ISA) – *retroperitoneal*
One 10/12-mm visual introducing cannula
One 5-mm curved electrocautery scissors
One 5-mm curved Maryland dissector
One 5-mm curved Harmonic scalpel and generator
One 10-mm locking Babcock
One 5-mm dolphin-nosed grasper
One 10-mm right-angled dissector
One 5-mm toothed locking grasper
One 5-mm electrocautery hook
Two 5-mm laparoscopic needle drivers (available in the room)
One 5-mm laparoscopic hand-piece for the argon beam coagulator and generator (available in the room)
One 5-mm diamond flex triangle retractor (Genzyme, Tucker, GA, USA) (available in the room)
One 10-mm PEER retractor (Jarit, Hawthorne, NY, USA)
One Martin arm (available in the room)
One 11-mm multiload clip applier (available in the room)
One 5-mm irrigator–aspirator
One grasping needle port closure device
One smoke evacuator valve (Plume-Away: Stryker Endoscopy, San Jose, CA, USA) (*optional*)
15F round Davol drain
One No. 15 blade scalpel and handle
Two fine-toothed pickups
One tonsil clamp
Two S-retractors
Three 0-Vicryl ties
Four 4-0 absorbable suture on a cutting needle
¼-inch steri-strips
Benzoin
Open nephrectomy surgical pan

Steps of the procedure

Step 1: Placement of an ureteral catheter

Some authors favor initial cystoscopic insertion of a ureteral catheter into the ureter draining the nondiseased moiety prior to performing the laparoscopic part of the procedure [141, 143]. Others do not believe this is a necessary step of the operation as the two ureters are often easy to differentiate at the time of laparoscopy [5]. The catheter does, however, aid in the identification of the normal ureter while dissecting out the dilated ureter draining the diseased moiety. It also allows injection of indigo carmine after excising the parenchyma of the upper or lower pole to help in the intraoperative identification of any inadvertent injuries to the normal collecting system of the remaining moiety. Recognition of this occurrence is important as it can usually be repaired laparoscopically and further complications can be avoided by placement of a drain with or without a stent.

For insertion of an external ureteral catheter, the patient is placed in the dorsal lithotomy position and a rigid or flexible cystoscope is utilized to introduce a 0.035-inch floppy-tipped wire under fluoroscopic control up the ureter of interest. A 6F open-ended catheter is then passed over the wire into the intrarenal collecting system. The wire is removed and contrast injected to confirm accurate positioning. The Foley catheter is inserted and the open-ended catheter is then secured to the Foley catheter using ½-inch steristrips and benzoin or several silk ties. A piece of intravenous line extension tubing is connected to the open-ended catheter and attached to a three-way stopcock on which a 60 mL syringe filled with methylene blue-colored saline (one ampule of methylene blue to 250 mL of sterile saline) is mounted. This allows easy access for injection during the laparoscopic procedure. A ureteral drainage bag is attached to the remaining port on the stopcock. The patient is then positioned for laparoscopic renal surgery as outlined for simple nephrectomy.

Step 2: Creation of the pneumoperitoneum and initial entry access

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach.

Step 3: Placement of secondary port sites

This step is identical to that outlined for the laparoscopic nephrectomy utilizing either a transperitoneal or retroperitoneal approach.

Step 4: Exposure of the retroperitoneum

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach. Mobilization allowing unobstructed access to the hilar structures is critical as dissection and securing of the upper pole blood supply is necessary, as is the ability to pass the transected ureter behind the renal artery and vein as described below for an upper pole heminephrectomy. Deep hilar visualization and identification of these structures is also important when resecting the lower pole system, although passage of the resected collecting system behind the vessels is not necessary [5].

Step 5: Identification and dissection of the upper or lower pole and ureter

The dilated upper or lower pole ureter is usually readily identifiable as a medial tortuous tubular structure, which may be intimately attached to the ureter draining the normal moiety. This latter structure can usually be differentiated by gently drawing an instrument across the surface of the suspected location of the ureter and feeling the resistive catch as it passes over the underlying stent. The two ureters can be intimately attached and the proximal aspect of the dilated system is dissected out with care taken not to injure the wall or vasculature supplying the normal system. Dissection and exposure of the hilar vessels is identical to that described for nephrectomy. In this procedure it is not necessary to transect the main renal vessels but to mobilize them as they cross anterior to the upper pole collecting system, and to identify and dissect out the branches supplying the upper or lower pole moiety.

Complete mobilization is facilitated by performing the dissection prior to transection of the ureter as distention of the diseased moiety often helps to define the correct plane. This dissection should continue until a right-angled clamp can be passed freely behind the vessels for an upper pole heminephrectomy. Gerota's fat is usually attenuated overlying the hydronephrotic moiety. The fascia is incised and Gerota's fat is split over the extent of the diseased segment. The Harmonic scalpel is utilized to separate the adrenal gland from the upper pole system when performing an upper pole heminephrectomy. Complete mobilization of the affected moiety to the edge of the normal pole parenchyma should be performed to facilitate eventual removal of the diseased portion of the kidney.

Step 6: Division of the ureter and vasculature of the involved moiety

The ureter is then transected at the point where it can be easily separated from the normal ureter to prevent

inadvertent injury to this structure. If the diseased ureter is associated with an obstructing ureterocele or an intermittently obstructing ectopic ureter which passes through the region of the bladder neck, the proximal end can be left open and all contained urine aspirated [142]. This allows for collapse of the remaining ureteral segment and prevents the establishment of a closed chamber of stagnant urine, which can lead to infection of the distal ureteral remnant. If reflux is present, most advocate removal of the involved ureter as distal as possible, leaving a strip of ureter attached to the normal ureter if necessary to prevent injury. The distal stump is then ligated or clipped adjacent to the bladder [5, 141]. Janetschek *et al.* advocate performing the distal ureteral dissection first prior to any renal manipulation [5]. Their rationale is that the likelihood of conversion is greatest during the renal part of the surgery and if an open flank incision is required after laparoscopic securing of the distal ureter, this approach saves the patient a possible second incision for the ureterectomy [5].

Once the ureter is transected, if the upper pole moiety is involved, the lowest portion of the exposed pelvis and lower ureter is grasped from above and is pulled up from behind the vessels. Additional connections between the hilar vessels and a portion of the pelvis may remain and are divided. If the lower pole is being removed, the hilar-based medial margin of the hydronephrotic moiety is identified and may lie close to the main renal vasculature.

Two 11-mm titanium clips or Weck interlocking clips are placed both proximally and distally on the arterial branches arising from the main renal artery or separately from the aorta to supply the involved moiety, and are dissected out as outlined above. The branches are then transected. Venous branches less than 4 mm in diameter can usually be secured using the Harmonic scalpel alone or with clips placed on the stay side to ensure adequate hemostasis. An Endo-GIA stapler can also be utilized to secure and divide more substantial polar vessels.

Step 7: Excision of the hydronephrotic remnant

The diseased remnant can usually be identified visually by its darkened poorly perfused appearance following transection of the polar vessels. It can also be delineated by palpation with the laparoscopic instruments, which reveals a more ballotable yielding character relative to the firmer quality of the normal renal parenchyma. The ureter and attached pelvis can be elevated and the moiety entered at the lateral juncture of the two poles away from the hilar structures. The Harmonic shears are ideal for removing the tissue of the diseased pole and providing adequate hemostasis. The edge of the resection is elevated and gently extended circumferentially, palpating opposite the planned line of incision to make certain normal parenchyma is appreciated at this level. Other devices such as the paddle cautery and argon beam coagulator can also be utilized to assist with hemostasis. On occasion, bleeding from the cut margin may be vigorous and unresponsive to the above noted measures. An absorbable suture on an SH needle may be introduced to place a figure-of-eight or short running suture to secure areas of bleeding. Knots are tied intracorporeally or, alternatively, the ends of the suture can be secured using Lapra-Tys (Ethicon Endo-Surgery),which are small absorbable Vicryl securing clips placed using a specially designed applier. Another alternative for removing the tissue and obtaining simultaneous hemostasis is to use the LigaSure (Valley Lab) bipolar vessel sealer for performing the resection of the hydronephrotic parenchyma in what has been reported to be a “bloodless resection” [145]. Others have described the use of the Endo-GIA stapler, which can be fired sequentially around the line of demarcation between the two poles or used to secure and divide the upper pole in a single firing of the Endo-GIA stapler [146]. The obvious potential complication with this latter approach is the creation of a small isolated chamber of urine with the potential for infection, although this apparently did not occur in the two renal units in which this method was utilized [146].

Step 8: Inspection for injury to the normal collecting system and drain placement

Once the specimen has been completely excised, it is placed above the spleen on the left or the liver on the right while further inspection and hemostasis is obtained. A member of the circulating personnel is then asked to use the previously assembled methylene blue irrigation set-up to inject blue-tinged saline into the collecting system [143]. Careful inspection of the bed of the resection site is performed laparoscopically to evaluate for any areas of normal collecting system injury. Any areas of leakage are closed using intracorporeal suturing and knot-tying or placement of the Lapra-Tys to secure the suture ends as outlined above. Small violations of the collecting system in regions where the surrounding tissue is insubstantial can be managed effectively by use of gel foam soaked in fibrin glue products [147, 148]. This requires that low pressures are maintained within the collecting system, which can be facilitated by converting the open-ended catheter to an indwelling double pigtail stent at the end of the procedure.

Step 9: Entrapment and removal of the specimen and drain placement

Once final inspection has been performed under both high and low insufflation pressures and hemostasis

is deemed adequate, the Carter–Thomason closure device is utilized to place a fascial closure stitch at all of the 10/12-mm port sites. If the amount of resected tissue is small, it may be possible to deliver it through one of the 10/12-mm port sites. For larger specimens, a ring-attached entrapment bag (e.g. EndoCatch I) can be utilized. The entrapment device is inserted through the lower quadrant 10/12-mm port site. An instrument is then passed via the epigastric/subcostal port and utilized to grasp the specimen to deliver it into the sac. The entrapment sac is then closed and drawn out through the port and the ring is detached. The port is removed and the bag with contained specimen is removed. If the bagged specimen is too large to fit through the established port incision, it is drawn up tight against the abdominal wall and judicious enlargement of the skin and fascial incisions is performed to allow delivery of the specimen. S-retractors are inserted to provide adequate exposure of the fascia once the skin incision is enlarged. A right-angled clamp can be inserted carefully at the corner of the incision with the backside of the right angle used to protect the bag. The electrocautery or Metzenbaum scissors are utilized to enlarge the incision, with great care taken not to incise or rupture the entrapment bag. The sac can be gently rocked back and forth to deliver it from the incision, while maintaining visual monitoring of the bag to ensure that it does not rupture and that advancement of the neck of the bag correlates with progression within and not simply stretching.

Some authors advocate placement of a postoperative drain [141. 143], while others do not [5, 142]. The perforated end of a 15F round Davol drain, with the spike removed and a clamp placed on the opposite end, can be advanced through the lateral-most 5-mm port and positioned in the retroperitoneum. The 5-mm port is removed and the drain is secured to the skin using a 3-0 Nylon suture.

Step 10: Exiting the abdomen, port closure, and ureteral catheter management

Once the specimen is delivered, the insufflation is turned off, the S-retractors are reinserted, and the previously placed full-thickness fascial closure stitch is placed on traction to facilitate placement of several additional closure stitches. A 0-Vicryl suture mounted on a UR-6 needle works well for this purpose. The pneumoperitoneum is then re-established and the organ extraction site reinspected. Provided the closure is adequate and no intraperitoneal structures are incorporated, the remainder of the port closure and exiting the abdomen process is identical to that previously described for laparoscopic nephrectomy.

If no collecting system injury to the normal moiety is demonstrated, the ureteral catheter may be removed at the end of the procedure [141] or left in place until the following day if dissection around the normal ureter was extensive or the orifice noted to be tight on cannulation. Male patients can be repositioned supine and female patients frog-legged to allow fluoroscopic exchange of the stent using a metal-tipped pusher when a collecting system injury is identified and repaired. The Benson 0.035-inch wire is inserted into the external ureteral catheter after its securing steri-strips or sutures are removed. The access catheter is removed and an appropriate sized stent is inserted, followed by a metal-tipped pusher, which is then advanced until the radio-opaque band is positioned at the level of the inferior edge of the pubic symphysis under fluoroscopic guidance. The wire is removed and pigtail formation in the renal pelvis and bladder confirmed.

Postoperative care

The postoperative care following laparoscopic heminephrectomy is identical to that for nephrectomy, with the only noteworthy exception being management of the external stent. If an external stent was placed at the beginning of the operative procedure and no obvious collecting system injury to the normal moiety was demonstrated, it may be removed at the end of the operation or the next day. If a collecting system injury was demonstrated and repaired intraoperatively, the catheter can be exchanged for a double-pigtail stent using a metal-tipped pusher under fluoroscopy at the end of the laparoscopic part of the operation. If a stent is inserted it is usually left in place for 1–2 weeks to allow adequate closure and healing of the collecting system repair.

If a drain was placed, output is monitored until it is less than 30 mL on two consecutive shifts following removal of the Foley catheter on postoperative day 1. If the drain output remains elevated, a drain fluid creatinine level should be checked. The patient can be sent out with the drain in place until outputs decline if fluid creatinine is markedly elevated above the serum level. Large outputs that persist beyond 1 week are usually a result of a substantial injury to the normal collecting system that was unrecognized or inadequately repaired, or it may be due to persistent production of urine from a retained portion of the resected moiety [149]. A retrograde pyelogram into the normal ipsilateral ureter will differentiate between these two clinical scenarios by demonstrating a leak in the case of an injury and no leakage if urine is being produced by retained parenchyma. Confirmation and management of this scenario can be made by selective angiography to demonstrate residual perfused parenchyma of the resected pole, which can then be embolized [149]. An alternative man-

agement option would be a repeat laparoscopic or an open exploration and repair.

Results

The first case of laparoscopic heminephrectomy for ureteral ectopia was reported by Jordan *et al.* in 1993 [141]. Janetschek *et al.* performed 14 laparoscopic heminephrectomies in 14 patients with a mean age of 5.4 years, all via a transperitoneal approach [5]. An upper pole heminephrectomy was performed in five children with an associated refluxing ectopic megaureter and two with an obstructive ectopic megaureter. Five patients had nonfunctioning hydronephrotic lower poles secondary to reflux nephropathy and two a nonfunctioning upper pole due to an obstructing ureterocele. The average operative time was 222 min in 12 cases undergoing heminephrectomy alone and 427 min in two cases combined with a Pfannenstiel incision through which an ureterocelectomy and reimplantation of the lower pole ureter was performed [5]. In this series, blood loss was minimal (10–30 mL) and the mean length of hospital stay was 4.4 days in the 12 patients undergoing laparoscopy alone and 7–8 days in the two patients who also underwent a reimplantation. This surprisingly long stay was thought to be a reflection of differing European standards for discharge. There were no significant intraoperative or postoperative complications reported.

More recently, Horowitz *et al.* reported their series of 14 laparoscopic upper pole heminephrectomies in 13 patients with a mean age of 3.8 years [142]. Twelve were associated with an ectopic ureter (two refluxing) and two with ureteroceles. All procedures were performed via a transperitoneal approach. Their mean operative time was 100 min for the unilateral procedures and 125 min for the bilateral procedures. The mean estimated blood loss was less than 30 mL with a length of hospital stay of 2.6 days. No major intraoperative or postoperative complications were reported. Wang *et al.* reported their series of four patients undergoing laparoscopic upper pole heminephrectomy for a poorly functioning upper pole segment associated with an ectopic ureter [149]. One patient developed a urinary fistula due to persistence of a small amount of functioning upper pole parenchyma, which was identified on superselective angiography and treated successfully with embolization.

Complications

All of the complications reported above for laparoscopic nephrectomy are possible following laparoscopic heminephrectomy. Although hilar dissection is required, as well as securing of the upper pole vasculature, major intraoperative or postoperative hemorrhage did not occur in any of the series mentioned above [5, 141, 142, 149]. Urinary leakage due to a lower pole collecting system injury was not reported in these series, although Wang *et al.* presented a case of persistent urine drainage from a retained portion of upper pole parenchyma that was confirmed on super-selective angiography and successfully embolized [149].

Cyst ablation

The goal of laparoscopic cyst ablation for patients with ADPKD, large solitary or peripelvic cysts is relief of symptoms generated by the compressive effects of the cyst. These cysts often take up significant amounts of the retroperitoneal space or are located medially within the hilum, making a transperitoneal exposure ideal for their management. A retroperitoneal approach to posterior-based cysts has also been described [150].

Instrumentation

The instrumentation required is listed in Table 81.7.

Steps of the procedure

Step 1: Placement of a ureteral catheter or administration of indigo carmine

Decortication of renal cysts that arise in, or extend deep into, a peripelvic location run the risk of entry into the collecting system. Recognition of this occurrence is important as it can usually be repaired laparoscopically and further complications avoided by placement of a drain with or without a stent. Two methods can be utilized to identify entry into the collecting system; one requires cystoscopic placement of a ureteral catheter at the beginning of the operation and repositioning, the other involves simple administration of indigo carmine prior to insufflation. If an external ureteral catheter technique is desired, a cystoscopic insertion and methylene blue irrigation system is performed identical to that described for laparoscopic heminephrectomy. The patient is then positioned for laparoscopic renal surgery as outlined for simple nephrectomy.

In the alternative technique, due to the relative oliguria that occurs during laparoscopic procedures, the indigo carmine will remain present within the collecting system for the duration of the procedure. Aspiration of the cyst with examination of the aspirated fluid for the presence of blue discoloration can be utilized to determine if the aspirated structure is a portion of the collecting system prior to decortication [151]. Compression of the renal pelvis with release of blue-tinged fluid after decortication confirms an injury to the collecting system and also helps to define its location. We prefer this method for peripelvic cyst decortication due to the thin

Table 81.7 Instrumentation required for cyst ablation (University of Wisconsin, Madison).

Standard rigid or flexible cystoscopic pan (*optional: peripelvic cyst*)
0.035-inch floppy-tipped wire (*optional: peripelvic cyst*)
6F open-ended catheter (*optional: peripelvic cyst*)
Ampule of indigo carmine (*optional: peripelvic cyst*)
Ampule of methylene blue (*optional: peripelvic cyst*)
Four non-bladed trocars:
• Three 5 mm and one 10/12 mm (with reducer) – no ultrasound anticipated
• Two 5 mm and two 10/12 mm (with reducers) – ultrasound anticipated
Two 10-mm laparoscopes: one 0° and one 30°
Two 5 mm laparoscopes: one 0° and one 30° (available in the room)
One 14G Veress needle
One 10/12-mm blunt-tipped cannula (available in the room)
One trocar-mounted balloon dilation device (Origin Medsystems, Menlo Park, CA, USA) – *retroperitoneal*
One 10/12-mm visual introducing cannula
One 5-mm curved electrocautery scissors
One 5-mm curved Maryland dissector
One 5-mm curved Harmonic scalpel and generator
One 10-mm locking Babcock
One 5-mm dolphin-nosed grasper
One 10-mm right-angled dissector
One 5-mm toothed locking grasper
One 5-mm electrocautery hook
Two 5-mm laparoscopic needle drivers (available in the room)
One 5-mm laparoscopic hand-piece for the Argon beam coagulator and generator (available in the room)
One 5-mm diamond flex triangle retractor (Genzyme, Tucker, GA, USA) (available in the room)
One 10-mm PEER retractor (Jarit, Hawthorne, NY, USA)
One Martin arm (available in the room)
One 11-mm multiload clip applier (available in the room)
One 5-mm irrigator–aspirator
One 10-mm laparoscopic biopsy forceps (Snowden-Pencer Inc., Tucker, GA, USA)
One 5-mm laparoscopic injecting needle
One 10-mm deflectable laparoscopic ultrasound probe (Tetrad, Tetrad Corp., Englewood, CO, USA)
One grasping needle port closure device
One smoke evacuator valve (Plume-Away: Stryker Endoscopy, San Jose, CA) (*optional*)
15F round Davol drain
One No. 15 blade scalpel and handle
Two fine-toothed pickups
One Tonsil clamp
Two S-retractors
Three 0-Vicryl ties
Four 4-0 absorbable suture on a cutting needle
¼-inch steri-strips
Benzoin
Open nephrectomy surgical pan

layer of separation between the collecting system and the base of the cyst that can be perforated during wire manipulations and catheter insertion (Figure 81.13). In addition, this latter technique obviates the need for repositioning of the patient, thus reducing overall operative times.

Step 2: Creation of the pneumoperitoneum and initial entry access

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach.

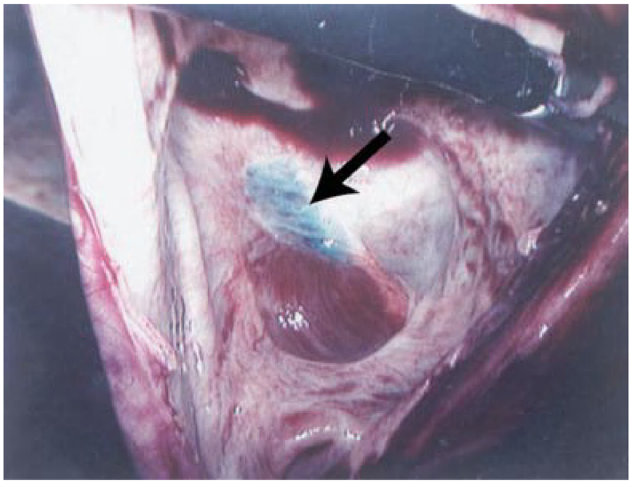

Figure 81.13 Collecting system identification during laparoscopic cyst decortication for a multichambered cyst with deep hilar extension. An ampule of indigo carmine was administered intravenously by the anesthesiologist prior to creation of the pneumoperitoneum. Note the blue-tinged urine that can be seen through the thin wall of the base of the cyst (arrow), yet no urine leakage is identified.

Step 3: Secondary port placement

There are no significant alterations to the secondary port placements as described for laparoscopic nephrectomy. Although an Endo-GIA stapler is not necessary for this operation, we maintain the left lower quadrant 10/12-mm port to use for the 10-mm lens and for removal of cyst wall specimens. Liver elevation is almost always necessary for right-sided procedures due to the cephalad extent or multiplicity of lesions requiring the lateral port as described for right-sided nephrectomies.

Secondary ports for the retroperitoneal approach are identical to those described for nephrectomy. If intraoperative ultrasound is anticipated, the 10/12-mm working port used to introduce the Endo-GIA stapler during nephrectomy can be utilized to insert the deflectable laparoscopic ultrasound probe.

Step 4: Exposure of the retroperitoneum

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach, as the majority of cysts requiring decortication are large or multiple and require access to all areas of the renal surface.

Step 5: Identification and exposure of cyst surface

Complete mobilization of the surface of the cyst wall from surrounding structures is easier to perform prior to decompression of the cyst unless exposure is limited due to its expanse. This is especially true for a large upper pole cyst on the right side secondary to overlap of the liver edge (see Figure 81.2A). Identification of a peripelvic or primarily intraparenchymal cyst can be difficult, especially in male patients with a thickened and adherent Gerota's fat layer. In such patients, use of a deflectable ultrasound probe can help to facilitate locating the margins of the cyst and guide the unroofing process. This may also prove helpful in identifying deeper parenchymal cysts during extensive decortications performed for ADPKD, or assessing wall nodularity within indeterminate cysts. Intraoperative ultrasound requires insertion via the 10/12-mm port in the left lower quadrant and moving the laparoscope to the periumbilical port site, which may require switching to a 5-mm lens if a 5-mm port was placed at this location.

Once the cyst has been exposed, confirmation that there is no connection with the collecting system should be established for a peripelvic or any cyst that extends deep along portions of the collecting system. This can be determined by puncture and aspiration using a laparoscopic needle inserted via the 5-mm port when indigo carmine was administered prior to insufflation or following a retrograde injection of methylene blue if a preoperative ureteral catheter was placed. The aspirated fluid can be placed on a clean surgical gauze to facilitate identification of a ring of blue staining when visual inspection of the syringe is equivocal secondary to pigment contained within the cysts. If concern exists regarding the possibility of malignancy, the aspirated cyst fluid can be sent for cytopathologic assessment.

It is important to make every effort to aspirate as much of the released material as possible from pigmented cysts associated with ADPKD since peritoneal contact with this material has been shown to result in a chemical peritonitis (Figure 81.14) [152]. If spillage occurs, contact areas are repeatedly irrigated using the irrigator–aspirator. The postoperative clinical course of these patients can be difficult to differentiate from patients suffering an unrecognized bowel injury and can also result in a profound ileus.

Step 6: Cyst unroofing, biopsy, specimen extraction

The Harmonic scalpel is the ideal device for unroofing large simple cysts, as well as multiple cysts associated with ADPKD because it limits bleeding from the cut edge of the cysts, yet minimizes collateral damage to structures such as the collecting system [129]. It is safest to begin opening the cyst at its thinnest point, which typically is found far from the edges. This is appreciated as a translucent appearing area that is often darker than surrounding regions of the kidney due to the underlying cavity. A laparoscopic aspirating needle can be inserted in this area as described above. Incision of the

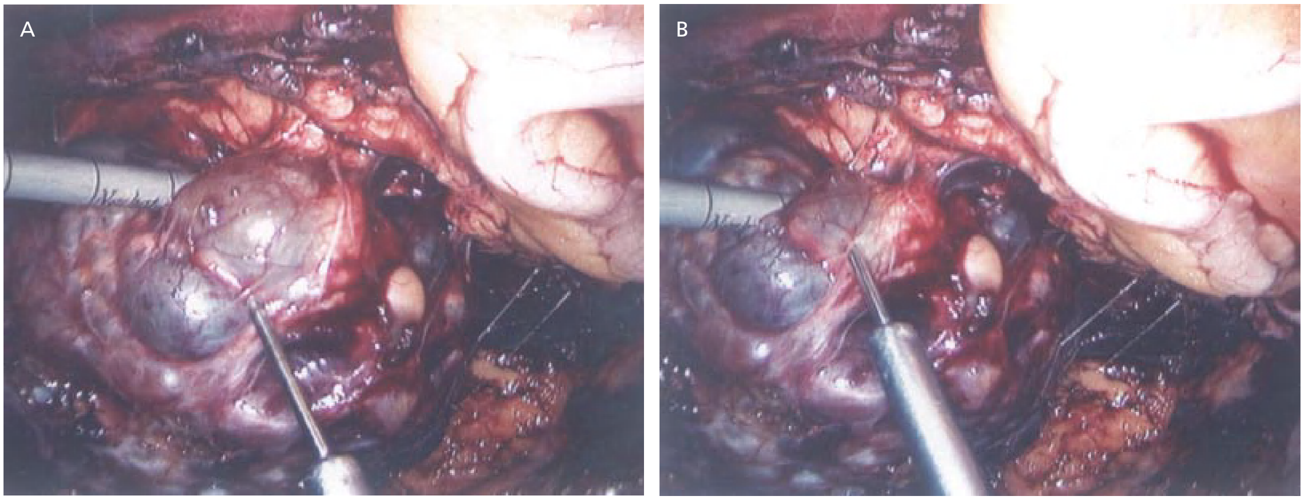

Figure 81.14 Laparoscopic cyst decortication in a patient with autosomal dominant polycystic kidney disease and numerous pigmented cysts. (A) To prevent postdecortication peritonitis syndrome induced by release of pigmented fluids into the peritoneal cavity, needle puncture of each pigmented cyst and (B) aspiration of its contents should be performed prior to unroofing with the Harmonic shears and thorough irrigation.

cyst wall is continued down to its border with normal parenchyma or collecting system, and the entire margin is circumferentially excised. This can be removed in sequential strips if a question exists regarding what is parenchyma and what is cyst wall. More vigorous edge bleeding often implies entry into normal parenchyma and can usually be controlled using the Harmonic device, bipolar electrocautery, pressure with a sheet of Surgicel, or the argon beam coagulator. On rare occasion, a figure-of-eight suture or a short interlocking running stitch along the edge may be required for hemostasis.

If a concern exists regarding the possibility of malignancy, as occurs with decortication of complex cystic lesions, the cyst fluid should be completely aspirated and sent for cytology. The excised cyst walls should be sent for pathologic inspection along with a biopsy of the base of the cyst. The cyst base biopsies are taken from regions that are not immediately adjacent to the collecting system. If a region of obvious thickening or nodularity is noted, specimens should be taken from these regions. Careful scrutiny of preoperative imaging studies can help locate areas of concern within the base of the cyst and guide sites for biopsy.

Smaller cyst wall and biopsy specimens can be removed directly via 10/12-mm ports. Larger cyst wall specimens for which there is no concern for malignancy can be cut into strips and removed through the 10/12-mm port. Alternatively, an EndoCatch I or II bag can be utilized to bag and remove the specimen. The EndoCatch I bag can be inserted via a 10/12-mm port, but requires ultimate removal of the port for specimen extraction. An EndoCatch II bag can be utilized when the specimen(s) is especially large, but requires initial removal of the port and insertion via the port incision. We prefer to perform specimen extraction via the lower quadrant port site as it is the most elevated in the flank position, preventing contact with bowel or deep intraperitoneal displacement of the specimen should a perforation of the bag occur. Morcellation can be performed as outlined for simple nephrectomy.

Decortication of all visible superficial and deeper cysts as well as final ultrasound inspection with a 10-mHz deflectable Tetrad ultrasound unit (Tetrad Corp, Englewood, CO, USA) to help identify any other previously unrecognized cysts within several millimeters of accessible surfaces has been advocated by several authors [8]. These additional cysts are also marsupialized, and the average number of cysts decorticated using this approach was 220 cysts per procedure in one review [8]. Due to the degree of mobilization and the resultant volume reduction following the procedure, some authors performed a postdecortication nephropexy in 77% of their patients using a 0 Polyglactin suture passed through the posterior abdominal wall fascia and capsule of the kidney, and secured at each end with a Lapra-Ty [8, 153]. This helps prevent hypermobility and torsion of the decompressed kidney on its hilar structures.

Step 7: Final inspection, exiting the abdomen, and port closure

Final inspection for hemostasis following cyst decortication is identical to that previously described for laparoscopic nephrectomy. In addition, the areas of

decortication and base biopsies should also be carefully inspected for evidence of urine leakage. If an externalized ureteral catheter was utilized, the circulating nursing staff or assistant can inject dilute methylene blue to help identify any leaks. If injected indigo carmine was utilized, gentle compression of the renal pelvis will assist in identifying any injury. An attempt at suture closure should be performed for all substantial collecting system lacerations utilizing a 4-0 Vicryl or Polydioxanone suture. Smaller injuries involving the calyces will often seal with stent drainage alone. Closure sutures are placed at each of the 10/12-mm port sites using the Carter–Thomason device. If a collecting system injury occurs, a 15F round Davol drain with the spike removed can be inserted via the 5-mm lateral port site. A clamp is secured to its end to prevent leakage of the CO_2 as it is fed into the abdomen and positioned in the retroperitoneum. The 5-mm port is then removed and the drain is secured to the skin using a 3-0 Nylon suture. The abdomen is desufflated, fascial entry sites are secured, and the peritoneal cavity is exited as previously described for laparoscopic nephrectomy.

If a collecting system repair was required, a ureteral catheter can be inserted at the end of the procedure. A simple stent exchange can be performed under fluoroscopy if an open-ended catheter was utilized without repositioning by utilizing a 0.035-inch floppy-tipped wire, a metal-tipped pusher, and an appropriate size stent. In this approach the stent is inserted, followed by the metal-tipped pusher, which is advanced to the inferior edge of the pubic symphysis, and the wire is removed under fluoroscopy, confirming proper position of the proximal and distal pigtails. If an external catheter was not utilized, the patient can be repositioned in the dorsal lithotomy, reprepped and draped, and a wire and subsequent stent introduced via the cystoscope in standard fashion. A Foley catheter is then inserted at the end of the procedure to minimize reflux along the stent.

Postoperative care

The immediate postoperative care of patients having undergone renal cyst decortication is identical to that after laparoscopic simple nephrectomy, with the following noteworthy exceptions. If a collecting system injury occurred and a drain and stent were inserted, the Foley catheter is left in place for 24 h provided the drain output is minimal (i.e. <30 mL/8 h). The Foley catheter is removed on postoperative day 2 and the drain output is monitored. If the drain output increases markedly, the source of the fluid can be evaluated by sending it for a creatinine level. If it is significantly above the measured serum creatinine level, then a portion of the fluid is urine and the Foley catheter should be left in place or replaced if it was removed. Once the Foley catheter has been discontinued and there is no significant increase in the drain output over the next 8-h shift, the drain can be removed. Patients are usually sent home on postoperative day 2 or 3. The stent is left in place for approximately 1 week and a retrograde pyelogram can be performed at the time of removal if concern exists regarding continued leakage.

The other exception to the standard postoperative care of patients following renal cyst decortication are those patients with ADPKD and a large number of hemorrhagic cysts. These patients can have a very protracted course secondary to a chemical peritonitis from the contents of the cysts and, as a result, can require up to 50% more parenteral analgesics than patients undergoing laparoscopic removal of their entire kidney [152]. The clinical postoperative presentation of these patients can include distention, diffuse abdominal pain, fever, elevated white blood cell count, and a profound ileus. In these patients, supportive care with intravenous fluids, pain medication, and tincture of time lead to ultimate resolution, although this can significantly prolong the hospital stay.

Results

Simple symptomatic parenchymal cysts

In a review of five series totaling 74 patients with large symptomatic cysts, the radiographic success rate of laparoscopic decortication was 90% over a mean follow-up of 7 months [6]. Lifson *et al.* reported their series of five patients undergoing cyst decortication for a symptomatic large cyst, with all five remaining pain free on a mean follow-up of 33 months [154]. Roberts *et al.* reviewed their series of laparoscopic decortication of large symptomatic parenchymal cysts in 21 patients [7]. Thirteen patients in their series had a transperitoneal and eight a retroperitoneal approach with a mean operative time of 164 min, operative blood loss of 98 mL, and a hospital stay of 1.9 days. They noted a 5% recurrence rate over a mean follow-up period of 15.8 months, although only 58% of the patients in their entire series underwent follow-up imaging [7].

Peripelvic cysts

Most reported series do not clearly delineate between peripelvic and parenchymal cysts. However, Roberts *et al.* compared their series of 21 parenchymal to 11 peripelvic cysts for which a laparoscopic decortication was performed [7]. A similar distribution of approaches (seven transperitoneal, four retroperitoneal) was noted for the peripelvic operations relative as was mentioned above for parenchymal lesions. There was a statistically significant longer mean operative time (233 min) and

blood loss (182 mL) noted for the peripelvic cyst decortications, which was felt to reflect the more technically challenging nature of this operation. Mean follow-up of 22.4 months did not demonstrate any evidence of recurrence. Not surprisingly, the percentage of patients with inadvertent entry into the collecting system was higher for the patients with peripelvic (18%) relative to simple parenchymal cysts (14.3%) [7]. Rubenstein *et al.* described one patient in their series of 10 laparoscopic cyst decortications with a large peripelvic cyst extending between the renal artery and vein. The cyst was decorticated and a wick of 6 x 1 cm polytetrafluoroethylene placed to help prevent reformation of the cyst [155]. This patient developed a small recurrent cyst, but remained asymptomatic at 10 months.

Hoenig *et al.* reviewed their experience of laparoscopic ablation of symptomatic peripelvic cysts in four patients [20]. Cyst size ranged from 4 to 6 cm and two patients had concomitant stone disease. Three of the four underwent a transperitoneal approach and one a retroperitoneal approach with a mean operative time of 338 min, estimated blood loss of 90 >mL, and length of stay of 2.75 days. One patient suffered a laceration of the renal pelvis, which was recognized and repaired intraoperatively. All patients had initial resolution of their preoperative pain, but one patient developed a symptomatic recurrence at 2 months requiring an open decortication. Another patient developed an asymptomatic recurrence of a 2-cm peripelvic cyst at 9 months.

Doumas *et al.* reported their series of five patients with peripelvic cysts ranging from 4.5 to 6.5 cm in size [156]. All underwent transperitoneal laparoscopic decortication with a mean operative time of 155 min and estimated blood loss of less than 150 mL. No intraoperative complications and only one minor postoperative complication (subcutaneous hematoma) occurred. All patients remained free of symptoms and radiographic evidence of obstruction at a mean follow-up of 23 months.

Indeterminate complex cystic lesions

Most surgeons advocate treating Bosniak IV (Table 81.1) lesions identical to cystic renal cancer due to the 90% risk of reported malignancy [6, 14, 15]. Controversy exists in the use of laparoscopy to evaluate and manage asymptomatic or symptomatic Bosniak II and III lesions with their associated 24% and 41% risk of malignancy. Even though completion nephrectomy can be performed when cancer is identified in resected wall segments or aspirated fluids, a case report by Meng *et al.* illustrates the possibility that laparoscopic decortication may alter the progression pattern of disease if it goes undiagnosed [16]. Their case had a symptomatic 20-cm Bosniak I lesion and underwent a laparoscopic cyst decortication. Analysis of the cyst wall demonstrated benign tissue. Seven months later the patient presented with a large renal mass involving the spleen and colon as well as liver, subcutaneous port site, lymph node, and peritoneal metastases. Pathology revealed Fuhrman grade 4 chromophil and sarcomatoid renal carcinoma [16]. The diffuse spread of disease over a relatively short period of time suggests that tumor spillage and possibly convection-related dissemination from the pneumoperitoneum likely contributed.

In contrast to this case, Santiago *et al.* reported their series of 35 patients who underwent laparoscopic assessment and management of Bosniak II and III lesions [17]. A total of five (14.3%) were discovered to harbor malignancy; four underwent immediate partial or radical nephrectomy and one a delayed partial nephrectomy. No recurrences were identified after a mean follow-up of 20.2 months. Roberts *et al.* described their series of laparoscopic management of renal cystic disease, which included eight patients with Bosniak II and III lesions [7]. One patient (12.5%) was identified on final pathology to have a small (<1 cm) focus of papillary renal cancer and underwent eventual open radical nephrectomy with excision of the trocar site used for specimen extraction. In a similar case, Lifson *et al.* discovered a small focus of papillary carcinoma in the cyst wall of a Bosniak I lesion and the patient underwent immediate open radical nephrectomy [154]. A prior negative cyst fluid aspiration cytology had been obtained on the patient and he remained free of disease recurrence at 58 months of CT scan follow-up [154].

The results of these last three series indicate that, in select patients with indeterminate cysts, laparoscopy may provide a reasonable diagnostic and therapeutic approach provided a careful inspection of the cyst base with biopsy, cytologic evaluation of aspirated fluid, and meticulous pathologic review of the resected cyst wall is performed. The finding of positive aspiration cytologies in only 14% of proven cystic malignancies [157] and the case report by Meng *et al.* [16] illustrate that accurate diagnosis at the time of laparoscopy may not be feasible and misdiagnosis may have a disastrous effect on the ultimate course of disease.

Autosomal dominant polycystic kidney disease

Symptomatic recurrence requiring repeat surgical therapy occurs more frequently following decortications performed for ADPKD, due to the multifocal, progressive nature of the disease. Subsequent treatment, including repeat laparoscopic decortication, cyst puncture with aspiration, and nephrectomy, is required in 10.3–37.5% of patients [8, 129, 154, 158]. Overall improvement in pain, bowel, or pulmonary complaints

Table 81.8 Results of laparoscopic cyst decortication in autosomal dominant polycystic kidney disease patients.

Series	Patients (proceedures)	TP/RP	Operative time (mean, min)	Analgesia (morphine equiv, mg)	LOS (days)	EBL (mL)	Transfusion (%)	*Symptomatic success*	Follow-up (mean, months)	Repeat treatment	Complications
Lee *et al.* [8]	29 (35)	33/2	294	61.1	3.2	124	0	>50% pain reduction 73% (12 months) 52% (24 months) 81% (36 months)	32.3	10.3%	3 (8.6%) – major 7 (20%) – minor
McNally *et al.* [129]	7 (8)	8/0	–	–	3.9	<200	25	51% pain reduction (14 months)	14	14.3%	3 (37.5%) – major

TP, transperitoneal; RP, retroperitoneal; LOS, length of stay; EBL, estimated blood loss.

has been defined and reported in variable fashion (Table 81.8). Lee *et al.* utilized analog pain scores to calculate the relative pain relief (RPR) value for each patient, which equaled (preoperative pain score) – (postoperative pain score)/(preoperative pain score). The RPR was calculated as 58%, 47%, and 63% at 12, 24, and 36 months, respectively. Greater than 50% reduction in pain was noted in 73%, 52%, and 81% of patients at 12, 24, and 36 months, respectively. These authors also showed significant improvements in six of eight quality of life domains 1 year following laparoscopic decortication [8].

Intrarenal ischemia from cyst growth, renal handling of sodium, inappropriate activity of the renin–angiotensin–aldosterone system, volume expansion, and increased atrial natriuretic peptide and plasma endothelin levels have been postulated to contribute to the hypertension noted in 50–70% of ADPKD patients before renal function is impaired [28]. Lee *et al.* evaluated the impact of laparoscopic decortication on hypertension in their patients using the antihypertensive therapeutic index (ATI), defined as [(dose of blood pressure medication 1/maximum dose 1) + (dose medication 2/maximum dose 2) + etc.] [8]. A total of five (23.8%) of the initial 21 patients with hypertension became normotensive following their procedure. Nine additional patients had a mean 49% improvement in their ATI; however, six patients had a mean worsening of 53%. The impact on creatinine clearance was also assessed using pre- and post-operative Cockcroft and Gault calculations of renal function, which demonstrated changes of +4%, +7%, and −2% at 1, 2, and 3 years, respectively [8].

Complications

The potential complications that can occur with cyst decortications include all of those mentioned previously for laparoscopic nephrectomy, with the exception of Endo-GIA malfunction. Complications that occur with greater frequency following decortication procedures include collecting system injury with resultant urinoma in as high as 8.5% of patients with ADPKD [8], 14.3% of simple parenchymal and 18% of peripelvic cysts [7]. Hemorrhage requiring transfusion occurred more commonly in patients undergoing decortication procedures in association with ADPKD (Table 81.8). Several of these cases were associated with the administration of heparin following concomitant insertion of a dialysis catheter [129]. The discovery of malignancy in less than 0.7% of simple cysts [15] and 12.5–14.3% of patients undergoing laparoscopic decortication for Bosniak II and III lesions [7, 17] could potentially lead to the catastrophic spread of disease, as described by Meng *et al*. [16].

Calycealectomy

The laparoscopic approach to stone-bearing calyceal diverticula is best suited to anterior-based lesions, as mentioned above under indications [159]. For this reason, we prefer a transperitoneal approach for this operation, although retroperitoneal exposure of the kidney with access and trocar distribution as described above has been described [160]. The purported advantages of the retroperitoneal approach are the lack of manipulation of the bowels, as well as the reduced potential for intraperitoneal extrusion of stone or infectious material.

Instrumentation

The instrumentation required for calycealectomy is listed in Table 81.9.

Steps of the procedure

Step 1: Placement of a ureteral catheter or administration of indigo carmine

This step is identical to that outlined above for renal cyst decortications when cysts closely approximate the collecting system.

Step 2: Creation of the pneumoperitoneum and initial entry access

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach.

Step 3: Secondary port placement

The only alterations to the secondary port placements as described for laparoscopic nephrectomy is the replacement of the periumbilical 10/12-mm port with a 5-mm port as Endo-GIA stapler insertion is not necessary. Ultimately, this will require the use of a 5-mm laparoscopic lens during placement of the stone(s) into the EndoCatch I bag and for fascial closure of the 10/12-mm port site. Depending upon the location of the diverticulum on the right, liver elevation may not be necessary, provided the lesion is located in the mid region of the kidney or the kidney sits lower in the retroperitoneum. This eliminates the need for the lower lateral port for right-sided procedures, which is used almost exclusively for liver elevation.

Secondary port placement for the retroperitoneal approach is identical to that described for nephrectomy, with the exception of replacing the 10/12-mm trocars

Table 81.9 Instrumentation for calycealectomy (University of Wisconsin, Madison).

Standard rigid or flexible cystoscopic pan
0.035-inch floppy-tipped wire
6F open-ended catheter
Ampule of indigo carmine
Ampule of methylene blue
Three nonbladed trocars – *left*; four nonbladed trocars – *right*:
• Two 5 mm and one 10/12 mm (with reducer) – *left* • Three 5 mm and one 10/12 mm (with reducer) – *right*
Two 10-mm laparoscopes: one 0° and one 30°
Two 5-mm laparoscopes: one 0° and one 30° (available in the room)
One 14G Veress needle
One 10/12-mm blunt-tipped cannula (available in the room)
One trocar-mounted balloon dilation device (Origin Medsystems, Menlo Park, CA, USA) – *retroperitoneal*
One 10/12-mm visual introducing cannula
One 5-mm curved electrocautery scissors
One 5-mm curved Maryland dissector
One 5-mm curved Harmonic scalpel and generator
One 10-mm locking Babcock
One 5-mm dolphin-nosed grasper
One 10-mm right-angled dissector
One 5-mm toothed locking grasper
One 5-mm electrocautery hook
One 5-mm laparoscopic needle drivers (available in the room)
One 5-mm tri-radiate grasping forceps
One 5-mm laparoscopic injecting needle
One 5-mm laparoscopic argon beam coagulation probe
One 10-mm PEER retractor (Jarit, Hawthorne, NY, USA)
One 11 mm multiload clip applier (available in the room)
One 5-mm irrigator–aspirator
One EndoCatch I bag (stone specimen removal)
One grasping needle port closure device
One smoke evacuator valve (Plume-Away: Stryker Endoscopy, San Jose, CA, USA) (*optional*)
One 5-mm diamond flex triangle retractor (Genzyme, Tucker, GA, USA) (available in the room – *right*)
One Martin arm (available in the room – *right*)
One No. 15 blade scalpel and handle
Two fine-toothed pickups
One tonsil clamp
Two S-retractors
Three 0-Vicryl ties
Four 4-0 absorbable suture on a cutting needle
¼-inch steri-strips
Benzoin
Open nephrectomy surgical pan

with 5-mm ports. Again, this will require the use of a 5-mm laparoscope for bagging of the stone specimen.

Step 4: Exposure of the retroperitoneum

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach, with the following exceptions. Complete splenic mobilization may not be necessary for diverticulum in the mid region of the left kidney as complete upper pole exposure is often unwarranted. Alternatively on the left, the line of Toldt can be incised around the splenic flexure, leaving the pancreas and spleen *in situ*. This usually provides adequate exposure and requires less dissection. On the right, the duodenum does not have to be kocherized unless it closely approximates the area of involved parenchyma as access to the great vessels is not necessary for this procedure.

Step 5: Renal dissection and identification of the diverticulum

A 30º 10-mm laparoscope is inserted through the 10/12-mm port in the lower quadrant for the transperitoneal approach. In the retroperitoneal approach, a 30º lens is also utilized via the 10/12-mm port off the tip of the 12th rib. The surgeon operates via the 5-mm ports utilizing the Maryland dissector held in the nondominant and the Harmonic shears in the dominant hand. If the location of the diverticulum on the right requires liver elevation for adequate exposure during the transperitoneal approach, the Diamond Flex Retractor is inserted through the lateral 5-mm port between the tip of the 12th rib and iliac crest. The retractor handle is twisted until the appropriate triangle configuration is obtained and it is then placed beneath the liver edge, elevated into position, and secured to the operating table utilizing the Martin robotic arm or an Endo-holder. Care should be exercised to prevent unnecessary pressure on the gallbladder or porta hepatis.

The kidney contained within Gerota's fascia and fat is usually easily identified by palpation of a firm structure in the retroperitoneum. The Harmonic shears are utilized to divide Gerota's fascia and fat overlying the lateral margin of the kidney, beginning at the lower pole and progressing cephalad. Frequent infections and inflammatory events may make exposure of the smooth capsular surface of the kidney difficult. The Harmonic device is ideal for performing this separation as it limits the amount of capsular oozing. The relative location of the calculus within the kidney is known as a result of the preoperative CT scan imaging confirming its regional position. The exact location is identified laparoscopically as a parenchymal indentation on the surface of the

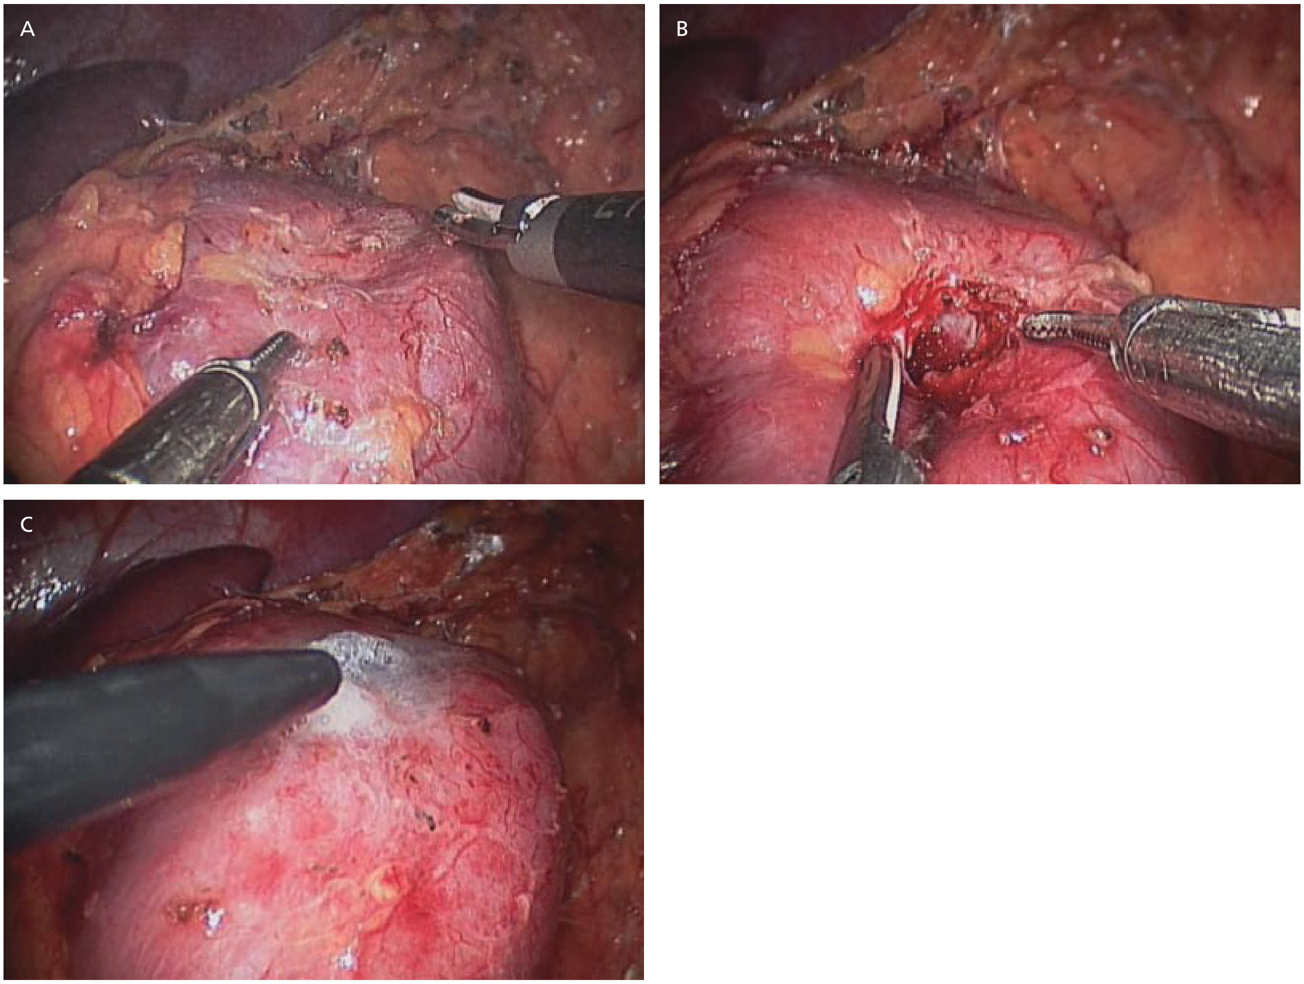

Figure 81.15 Laparoscopic calycealectomy. (A) An indentation on the surface of the renal parenchyma marks the location of the diverticulum. (B) Harmonic shears are utilized to unroof the overlying parenchyma. (C) The small ostium of the diverticulum is occluded utilizing fibrin glue products.

kidney [160] (Figure 81.15A), although this area can also appear raised relative to the surrounding parenchyma [159]. If inflammatory events have occurred within the diverticulum, the overlying fat may adhere to and fill the parenchymal depression. This can be probed with a laparoscopic aspirating needle to confirm the presence of the underlying stone as a hard area of contact feedback. Theories regarding thinning of the parenchyma in this region include a lack of induction of the metanephric blastema in this region for those who believe in congenital origins versus resultant scarring and atrophy from inflammation [36–38].

Step 6: Incision of the diverticulum and stone extraction

Regardless of the origin, the parenchyma in this region is usually thin and devoid of significant blood supply, allowing incision with the electrocautery or Harmonic shears (Figure 81.15B) without marked hemorrhage [160]. Once the overlying parenchyma has been incised, the diverticulum is irrigated gently to reveal the contained stone. The 10-mm laparoscope is exchanged for the 30º 5-mm lens, which is inserted in the subcostal region for the transperitoneal approach and in the posterior axillary line 5-mm port for the retroperitoneal approach. The EndoCatch I bag is introduced via the 10/12-mm port and the other 5-mm port is utilized to extract the stone(s) using the percutaneous three-prong graspers and to place all stone material into the entrapment sac (Figure 81.16). The drawstring is then pulled tight on the sac, the port is removed, and the drawstring clamped near the skin level. The stones within the entrapment sac are left *in situ* within the peritoneum or retroperitoneum, and the port is then reintroduced.

Figure 81.16 Laparoscopic calycealectomy and stone extraction. (A) The thinned area of parenchyma has been incised and the stone can be visualized as it is being engaged utilizing the three-prong percutaneous stone graspers. (B) The stone is extracted from the diverticulum and deposited into an entrapment sac.

Step 7: Diverticulum ablation and closure of collecting system

The diverticulum is inspected to find its communication with the collecting system. Identification is facilitated by injection of methylene blue via the externalized ureteral catheter or by gentle compression of the renal pelvis if preinsufflation indigo carmine was utilized instead. Both techniques result in a stream of blue-tinged urine emitting from the area of the connection. If the opening is not identified using these techniques, then it is likely extremely small and fulguration of the area alone or application of fibrin glue products (see Figure 81.15) will usually suffice to prevent leakage of urine. The 5-mm laparoscopic argon beam coagulator is ideal for complete ablation of the urothelial lining of the diverticulum, although the back of the electrocautery or Harmonic shears can also be utilized. Once the entire surface has been ablated, a 3-0 Vicryl on an RB-1 needle is inserted via the 10/12-mm port and a figure-of-eight closure suture is placed across the mouth of the diverticulum. Repeat injection of methylene blue via the externalized stent (or compression of the pelvis if intravenous indigo carmine is utilized) confirms a watertight closure.

One option when a large, gaping cavity is created that is unlikely to collapse following fulguration, is to insert a tongue of Gerota's fat into the base of the diverticulum. It is then secured with one or more sutures of 3-0 Vicryl to the wall of the diverticulum utilizing intracorporeal suturing techniques.

Step 8: Exiting the abdomen, drain placement, and port closure

The area of the dissection is inspected for hemostasis once again at low insufflation pressures and all bleeding points are cauterized. The perforated end of a 15F round Davol drain with the spike removed is inserted, via the lower quadrant port in the transperitoneal approach and the lateral-most port in the retroperitoneal approach. Placing a clamp on the back-end of the drain prevents release of the pneumoperitoneum during this maneuver. A grasper is inserted via the port used to bag the specimen and is utilized to position the drain lateral and behind the kidney to monitor for any leakage of urine. The specimen is removed under vision of the 5-mm laparoscope inserted via the remaining 5-mm port with the fascial incision enlarged if necessary. If enlargement of the fascial site is not anticipated, then the fascial closure needle can be utilized to place a closure stitch at the port site prior to insertion of the drain. The final port is removed as previously described after evacuation of the pneumoperitoneum. As with other retroperitoneal procedures, the blunt-tip trocar site is usually closed under vision while the fascial incisions of the 5-mm ports are not sutured. The skin incisions are closed as previously described.

Postoperative care

The postoperative care following laparoscopic calycealectomy is identical to that for cyst decortication. If an

external stent was placed at the beginning of the operative procedure, it is removed at the end of the operation or exchanged for a double-pigtail stent using a metal-tipped pusher under fluoroscopy when closure of the ostium of the diverticulum is in question. The drain output is monitored until it is less than 30 mL on two consecutive shifts following removal of the Foley catheter on postoperative day 1. If the drain output remains elevated, a drain fluid creatinine level should be checked, and if it is markedly elevated above serum levels, the patient can either be sent out with the drain until outputs decline, or a double-pigtail stent can be inserted if large volume urine-laden drainage continues. If a stent is inserted, it is usually left in place for 1 week to allow adequate coaptation and closure of the mouth of the diverticulum.

Results

There have been limited published series on laparoscopic calyceal diverticulectomy with reported stone-free and diverticulum obliteration rates of 92–100% with short follow-up (<1 year) [159–161]. Approaches utilized in the literature are split between the transperitoneal and retroperitoneal approaches with mean operative times of approximately 130 min [160].

Complications

Any of the intraoperative or postoperative complications related to access entry, retraction, dissection, or port closure as described for simple nephrectomy are possible with laparoscopic diverticulectomy. The one exception is no risk of a major vascular event secondary to Endo-GIA stapler misadventure because no major vascular structures should require transection during this procedure. A total of three complications among five patients who underwent laparoscopic calyceal diverticulectomy have been reported in the literature. One patient had a significant hemorrhage requiring a 3-unit blood transfusion [160]. This presumably occurred at the site of incision of the diverticulum. Another had a persistent discharge from their port site for 2 months [160]. The source of this prolonged drainage was not detailed further and was said to resolve spontaneously without any described intervention. Another patient was noted to have prolonged crepitance, which was thought to be a result of using the argon beam coagulator since it persisted for 1 week, which exceeds what would be expected from rapidly absorbed CO_2 [38].

Another potential complication, not reported in the literature, which has occurred following laparoscopic diverticulectomy is a persistent urine leak or urinoma development in the flank (T.J. Moon, personal communication). This results from either inadequate suture closure of the neck of the calyceal diverticulum or inadvertent dissection into the collecting chamber at a site other than the connection. Drainage usually abates rapidly following insertion of a ureteral stent. If stent placement is unsuccessful in resolving a urinary fistula, more invasive methods extrapolated from similar scenarios following partial nephrectomy such as percutaneous drainage, tissue adhesive injection, or open exploration could be required [162, 163].

Nephropexy

In 1993, Urban *et al.* reported the first case of laparoscopic nephropexy for the treatment of clinically significant nephroptosis [164]. It has since been shown to be equally efficacious with superior postoperative pain, morbidity, and convalescence in comparison to the open approach [54]. Laparoscopic fixation of the kidney to the quadratus lumborum fascia can be accomplished via a transperitoneal or retroperitoneal exposure. We, along with other groups, advocate upper pole fixation to the cut margin of the coronary ligament of the liver, which is best accomplished via a transperitoneal exposure [165]. A retroperitoneal exposure with fixation to the quadratus fascia only has been described with the port distribution as outlined for retroperitoneal nephrectomy [166]. As previously mentioned, the majority of nephropexy procedures are performed on the right with only 10% of cases isolated to the left kidney [49, 59].

Instrumentation

The instrumentation required for nephropexy is listed in Table 81.10.

Steps of the procedure

Step 1: Creation of the pneumoperitoneum and initial entry access

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach. Care must be exercised in these cases on initial entry with the Veress needle in the lower quadrant as the kidney can be displaced into this area in some cases of extreme mobility. Usually air-planing the table slightly away from the operating surgeon will cause the kidney to roll into a more normal location.

Step 2: Secondary port placement

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach with the exception that only the periumbilical port needs to be a 10/12-mm port to

Table 81.10 Instrumentation required for nephropexy (University of Wisconsin, Madison).

Four nonbladed trocars: three 5 mm and one 10/12 mm (with reducer)
Two 10-mm laparoscopes: one 0° and one 30°
Two 5-mm laparoscopes: one 0° and one 30° (available in the room)
One 14G Veress needle
One 10/12-mm blunt-tipped cannula (available in the room)
One trocar-mounted balloon dilation device (Origin Medsystems, Menlo Park, CA, USA) – *retroperitoneal*
One 10/12-mm visual introducing cannula
One 5-mm curved electrocautery scissors
One 5-mm curved Maryland dissector
One 5-mm curved Harmonic scalpel and generator
One 10-mm locking Babcock
One 5-mm dolphin-nosed grasper
One 10-mm right-angled dissector
One 5-mm toothed locking grasper
One 5-mm electrocautery hook
One 5-mm laparoscopic needle drivers
One 5-mm laparoscopic argon beam coagulation probe
One 10-mm PEER retractor (Jarit, Hawthorne, NY, USA)
One 11-mm multiload clip applier (available in the room)
One 5-mm irrigator–aspirator
One grasping needle port closure device
One smoke evacuator valve (Plume-Away: Stryker Endoscopy, San Jose, CA, USA) (*optional*)
One 5-mm diamond flex triangle retractor (Genzyme, Tucker, GA, USA)
One Martin arm (available in the room)
One No. 15 blade scalpel and handle
Two fine-toothed pickups
One tonsil clamp
Two S-retractors
Three 0-Vicryl ties
Four 4-0 absorbable suture on a cutting needle
¼-inch steri-strips
Benzoin
Open nephrectomy surgical pan

enable insertion of the needle-mounted sutures, whereas all others can be substituted with 5-mm ports. This requires the use of a 5-mm laparoscopic lens. Alternatively, the same port sizes and configuration for laparoscopic nephrectomy can be utilized for this procedure, allowing use of the 10-mm laparoscope if desired.

Step 3: Exposure of the retroperitoneum

This step is identical to that outlined for laparoscopic nephrectomy utilizing either the transperitoneal or retroperitoneal approach. In the transperitoneal approach it is not necessary to kocherize the duodenum as access to the hilar vessels is unnecessary and this structure is widely separated from the lateral margin of the kidney. The Genzyme liver retractor is inserted via the lateral-most port and is utilized by the assistant surgeon to elevate the liver edge to expose the coronary ligament. Care should be exercised when transecting the infrahepatic peritoneal attachments to the liver to leave enough of a shelf-like edge beneath which the upper pole of the kidney can be inserted and two securing sutures to the renal capsule placed as described by Elashry *et al*. [165].

Step 4: Exposure of the renal capsule and quadratus fascia and patient positioning

Once the kidney is exposed within Gerota's fascia, it should be elevated back into its standard position as it may be found flipped into a medial or inferior location. Appropriate positioning of the kidney in the retroperitoneum is facilitated by placing the patient into a deep Trendelenburg position and air-planing the table away from the operating surgeon. The lateral and superior border of the kidney are identified, Gerota's fascia is incised over this area, and the anterior fat is peeled back from the surface of the kidney while several centimeters of the posterior layer of fat is excised to expose the capsule of the kidney. The contact region between the edge of the kidney and the retroperitoneal fat is noted and the Harmonic shears are utilized to remove all of the fat overlying this region, so the broad fascial surface of the quadratus musculature is available for suturing (see Video 81.1). The lack of intervening fat allows for better visualization during suture placement through the quadratus fascia and renal capsule, and creates better contact between the surfaces of these structures. The use of an intervening strip of Gerota's fat as a bolster over which the securing sutures are tied can result in necrosis of the fat and resultant mobility. Differing thickness of fat bolsters can also result in poor contact points, stress at the remaining sutures, tear outs, and subsequent failure of the procedure.

Step 5: Bolster preparation and suturing

Two-inch Surgicel bolsters are created by rolling cut segments and securing each end with a 3-0 Vicryl tie. Nephropexy sutures are spaced approximately 1½ inches apart, so a total of two sutures are tied down over each bolster. Longer bolsters can be utilized, but are more cumbersome. We prefer to use 2-0 silk suture mounted on a SH needle for our nephropexy stitches due to its permanence, induced tissue response, and ease of tying. The SH needle is ideal for this procedure due to its tapered point and relatively flat curvature, allowing gentle, yet lengthy passage beneath the renal capsule. Each suture is cut into a 7-inch length, which is optimal for throwing a single intracorporeal suture.

The upper pole of the kidney is secured to the cut edge of the infrahepatic peritoneal edge by placing two sutures, first through the peritoneum and then through the adjacent region of renal capsule. This step is the reason why it is important to cut the peritoneum low enough to leave an adequate shelf beneath which the upper pole can be inserted and sutured. Care should be exercised to place these renal capsular sutures just where the convexity becomes the anterior surface of the upper pole, as more posterior placement will force the kidney into slight anterior rotation. While these sutures are being placed, the patient remains in the deep Trendelenburg position with full lateral rotation to help keep the kidney in its anatomic position. The assistant utilizes the Genzyme liver retractor to elevate the liver edge to expose this region for suture placement. The needle is passed initially from outside-to-inside through the infrahepatic peritoneal edge, and is pulled through to the appropriate length prior to passage through the capsule of the kidney to prevent sawing through this delicate structure (see Video 81.2). The needle is scythed just below the capsule for as long a length as the arc of the needle will allow. Care must be exercised to avoid entry into the substance of the renal parenchyma, which can result in vigorous and persistent bleeding, making visualization during the operation difficult. A second suture is then placed in identical fashion approximately 1½ inches medial to the first. Prior to tying either suture, a 2-inch Surgicel bolster is placed between the capsule of the kidney and the cut infrahepatic peritoneal edge (see Video 18.3). This not only aids in hemostasis, but stimulates tissue reaction and clotting between the two structures with eventual fibrous fixation. These sutures are then carefully tied down over the bolsters to a degree of visual tension that brings both into firm contact with the bolster, but is not enough to lacerate the capsule.

Once these sutures are placed, the operative assistant removes the Genzyme retractor and replaces it with a blunt instrument such as the irrigator–aspirator. This instrument is then utilized to provide temporary liver elevation, when necessary, but to more importantly provide lateral kidney retraction while the sutures are being planned and tied down. This is especially important when tying down the sutures on the convexity of the lower pole. The kidney is first held into position by the assistant and, beginning along the lateral border of the upper pole, the site for fascial and renal capsular suture placement is then mentally visualized and the assistant relaxes retraction of the kidney enough to allow better exposure of these surfaces. The sutures are then placed first through the quadratus fascia and then through the capsule of the kidney. A second suture is then placed approximately 1½ inches lower on the convexity of the kidney, and a Surgicel bolster is then positioned between the quadratus fascia in this area and the capsule of the kidney. The assistant then retracts the kidney into its appropriate position and the sutures are sequentially tied down over the bolster as described above (see Video 81.4). The process is then repeated until the kidney is firmly fixed to the quadratus fascia. This usually requires approximately four or five laterally-based sutures in addition to the two that were placed through the infrahepatic peritoneal edge (Figure 81.17).

Fornara *et al.* described a similar technique but placed only a single nonabsorbable polyester suture through the upper pole and a second through the convexity of the kidney, fixing each to the quadratus fascia [53]. McDougall *et al.* utilized a braided polyester suture

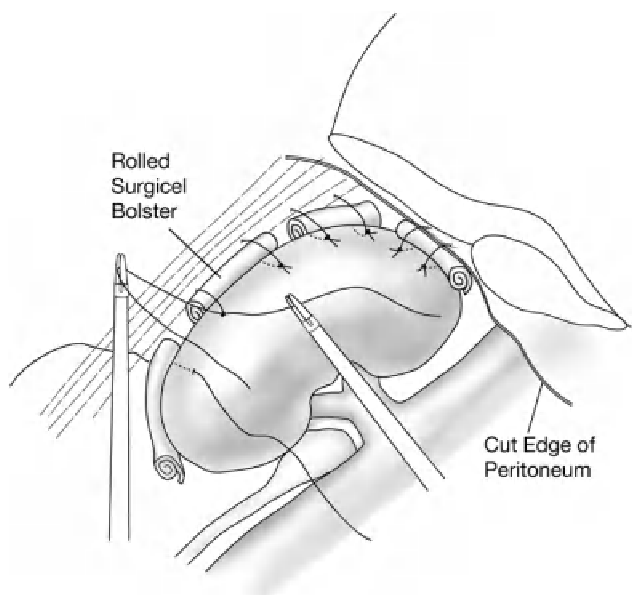

Figure 81.17 Right laparoscopic nephropexy. Two sutures are placed at a time through the quadratus fascia and renal capsule, and are tied over rolled Surgicel bolsters.

with a preformed loop on the end [58]. The suture-mounted needle is passed initially through the capsule of the kidney, then through the quadratus fascia, and the needle is brought through the loop to allow cinching into place. Once all of the securing sutures have been placed utilizing this technique, they are then tightened and secured using a Lapra-Ty suture clip (Ethicon Endo-Surgery). The cephalad-to-caudal approach for suture placement and securing of the kidney allows fixation to occur first in the areas of least tension and proceeds toward the area of maximum tension in the lower pole.

Instead of tacking sutures, Plas *et al*. utilized a polypropylene mesh shaped like an ellipse to cover the kidney in its sagittal extension and then secured the mesh to the abdominal wall with staples [59]. Previously, an absorbable Polyglactin mesh had been utilized for their initial six patients; however, this was ultimately abandoned after a patient developed symptomatic recurrent mobility 3 months following surgery [59].

Step 6: Exiting the abdomen and port closure

After tying the final suture, the operating table is returned to its neutral position and the kidney is visually monitored to ensure that it maintains its fixed position in the retroperitoneum. Final inspection of the areas of dissection for hemostasis, exiting the abdomen, and port site closure are then performed in identical fashion to that described for laparoscopic nephrectomy.

Postoperative care

The immediate postoperative care for patients having undergone nephropexy is identical to that described following laparoscopic simple nephrectomy, with the following exceptions. The patient is usually kept in a supine position overnight to prevent tension at the securing sutures and to allow clotting to begin in the region of the Surgicel bolsters. Postoperative immobilization following open nephropexy procedures has ranged from 1.5 to 10 days with resultant success rates of 36.3–94.1% [167–170]. Fornara *et al.* noted no difference in success rates following immobilization for 3 days in their initial 11 patients and their next 12 patients who were immobilized anywhere from 1 to 3 days [54]. This series and our own experience indicate that protracted immobilization following the procedure is not necessary. Ambulation is initiated the following day and once the patient has demonstrated stable mobility, the Foley catheter is removed. If bowel sounds are present, the diet can usually be advanced rapidly due to the limited mobilization of the bowel.

The patient is typically discharged home on postoperative day 1 or 2 and is instructed to refrain from all "vertical jarring" activities such as jogging, horseback riding, etc. for 4–6 weeks to allow stable fixation of the kidney. A follow-up nuclear renal scan is then performed in the sitting position and is compared to the patient's preoperative sitting images. This should demonstrate a postoperative position of the kidney in the sitting position nearly identical to the supine images and resolution of any previously demonstrated reduction in 1–2 min perfusion, relative renal function, or tracer excretion (see Figure 81.3).

Results

The long-term results of four of the larger published series of laparoscopic nephropexy (Table 81.11) reveal that symptomatic improvement or cure is noted in 92–100%, with radiographic improvement in 90–100% of those with sufficient follow-up using suturing and mesh graft fixation techniques [54, 58, 59, 170]. In Plas et al.'s series, one of 30 patients developed a symptomatic recurrence when she felt a "tearing" sensation in her flank during vigorous exercise 3 months following her surgery, and once again developed symptomatic nephroptosis [59]. This was one of the patients who had an absorbable mesh graft fixation performed. A comparison of 23 laparoscopic to 12 prior open nephropexy procedures performed at a single institution demonstrated only slightly longer mean operative time of 61 min versus 49 min, but reductions of postoperative pain medication (15 mg vs 38 mg morphine equivalent), mean hospital stay (3.7 days vs 16 days), and complications (13% vs 33%) for the laparoscopic relative to the open approach [54].

Complications

As with the other renal laparoscopic procedures, any of the intraoperative or postoperative complications related to access entry, dissection, or port closure as described for simple nephrectomy are possible with laparoscopic nephropexy, with the exception of Endo-GIA stapler misadventure. Summarizing the laparoscopic series outlined in Table 81.11, complications include bleeding requiring blood transfusion (2.5%), minor retroperitoneal hematoma (1.7%), urinary tract infection (0.8%), nausea/vomiting (0.8%), and symptomatic recurrence (0.8%) [54, 58, 59, 170]. Other complications reported for open nephropexy, though not occurring in these series, remain theoretic possibilities and include genitofemoral entrapment or neuralgia, costal osteomyelitis, hydronephrosis, and obstruction or stenosis of the UPJ [54, 55, 171]. Another potential risk when utilizing a permanent mesh would be the risk of

Table 81.11 Results of laparoscopic nephropexy.

Series	Technique	TP/RP	Operative time (mean, min)	Analgesia (morphine equiv, mg)	LOS (mean, days)	Radiographic success	Symptomatic success	Follow-up	Complications
Plas *et al.* [59]	Mesh graft	30/0	154	16	6	9/10 (90%)	11/13 (85%) cured	5.9 years (median)	1 symptomatic recurrence
McDougall *et al.* [58]	Suturing	12/2	246	37	2.6	13/14 (92.8%)	21% cured 71% improved	3.3 years (mean)	1 vomiting and dehydration
Fornara *et al.* [54]	Suturing (two sutures)	23/0	49	15 and 550 mg ibuprofen	3.7	23/23 (100%)	91% improved 2 not accessed	13 months (mean)	3 (13%) 1 UTI 2 retroperitoneal hematoma
Gozen *et al.* [170]	Suturing (two sutures)	0/51	95	4 patients only- 35 mg; all diclofenac	8 (median)	48/51 (94.1%)	95% cured 7 not accessed	98 months (mean)	3 blood transfusion

TP, transperitoneal; RP, retroperitoneal, LOS, length of stay; UTI, urinary tract infection.

Table 81.12 Key points.

- Equal efficacy with improved postoperative analgesia requirements, hospital stay, and convalescence have been demonstrated for most laparoscopic renal procedures for benign disease relative to their open counterparts
- A transperitoneal or retroperitoneal approach can be utilized for most laparoscopic renal procedures and is largely dependent upon surgeon preference and training
- The Harmonic scalpel is an extremely helpful adjunct instrument for performing laparoscopic renal surgery
- Laparoscopic nephrectomy is an accepted and effective option for most benign conditions requiring removal of the kidney, with the possible exceptions of xanthogranulomatous pyelonephritic and tuberculous kidneys
- Laparoscopic heminephrectomy can be performed for duplication-associated anomalies when a symptomatic, poorly functioning upper or lower pole moiety is affected
- Preoperative cystoscopic placement of a ureteral catheter for intraoperative methylene blue collecting system injection is helpful when performing laparoscopic heminephrectomy, peripelvic cyst ablation, or calycealectomy
- Laparoscopic decortication of simple, peripelvic, and ADPKD-associated renal cysts is an excellent first-line treatment option with durable symptomatic improvement
- Laparoscopic peripelvic cyst decortication is associated with a higher rate of collecting system injury and there is no consensus regarding the safety of laparoscopic decortication of Bosniak II and III category cysts
- Laparoscopic calycealectomy is best suited for anterior-based, stone-bearing calyceal diverticula
- Laparoscopic nephropexy has >90% radiographic and 85% symptomatic success rates on mean follow-up of >3 years in several series

infection or rejection of the mesh, which was reported to be 1% in a review of 500 cases during which it was used for hernia repair [59, 172].

Conclusions and key points

Nearly 20 years after Clayman *et al*. ushered in the new era of laparoscopic surgery in urology with their report of the first case of laparoscopic nephrectomy [173]. The procedure is now commonplace at many university and community hospitals. Increased experience with this operation has resulted in a more refined understanding of the anatomy and ergonomics of laparoscopic renal surgery, leading to further application to other forms of benign disease. Partial extirpative and reconstructive renal procedures, such as heminephrectomy, renal cyst ablation, calycealectomy, and nephropexy, are now being performed laparoscopically with regularity, and have led to improvements in postoperative morbidity and convalescence similar to laparoscopic nephrectomy. In the process, urologists have had to familiarize themselves with physiologic responses, anatomic exposures, and complications that are unique to the laparoscopic approach. The key points are summarized in Table 81.12.

The expansion of patient educational materials available via the Internet, health maintenance organizations seeking shorter hospital stays, and the desire for employers to minimize periods of convalescence have further fueled the growth of laparoscopic renal surgery. Technologic advances in instrumentation, robotics, tissue welding, hemostatic agents, and ablative devices have already begun to impact how we are currently performing these operations. These advances combined with the limitless vision of the urologist's mind will ultimately determine how the term "minimally invasive renal surgery" is defined in the next 20 years.

CHAPTER 82
Laparoscopic Living Donor Nephrectomy

Jonathan D. Harper,[1] Alberto Breda[2] & Peter G. Schulam[3]

Introduction

Following the description of living laparoscopic donor nephrectomy (LLDN) in 1995, the procurement of kidneys has changed dramatically [1]. This change in technique has paved the way for increased living kidney donation. In fact, the United Network of Organ Sharing (UNOS) reported that the number of living donations performed in the USA exceeded the number of deceased donations for the first time during the year 2000. The addition of hand-assisted techniques has also arguably increased the transition from open to laparoscopic procurement in many centers. During the initial decade following the first LLDN, from 1995 to 2004, the number of living kidney donations increased from 3395 to 6647 according to the Organ Procurement and Transplantation Network (OPTN) Scientific Registry of Transplant Recipients (SRTR) annual report. Since that time, the number of living kidney donors decreased over the next 4 years to approximately 6000. Resurgence in the number of living donors was seen in 2009 and reported to be 6388 at this time (Figure 82.1). The laparoscopic approach has decreased some disincentives to donate and, depending on hospital volume and surgeon experience, there are few remaining indications for open donor nephrectomy.

Preoperative evaluation

Any potential living kidney donor must undergo extensive medical evaluation to rule out medical comorbidities and to try to lessen the chance that the donor is in need of renal replacement therapy in the future. This medical evaluation typically centers on a transplant nephrologist. It is also routine for potential donors to undergo a psychologic evaluation to deem whether they are fit mentally for donation and to assess for any coercion involved. It is important for any patient for whom donation is not straightforward because of medical reasons, surgical anatomy, or social reasons, to be presented in a multidisciplinary conference, which may consist of the donor coordinator, nephrologists, donor and transplant surgeons, and genitourinary radiologist.

The evaluation by the donor surgical team is an important part of the process as it allows for selection of the surgical technique to be employed, identification of the appropriate kidney for donation, and proper consultation regarding the risks of kidney donor surgery. The surgical evaluation provides an additional opportunity to identify issues that may have not been revealed during prior visits, as well as to focus on the details specific to donor surgery. The recipient identity, their relationship to the donor, and the cause of their renal failure is reviewed. Particular attention is focused on whether the patient has any urologic history, such as gross hematuria, nephrolithiasis, pyelonephritis, renal cysts or tumors. At times, new issues may come up at this visit, or perhaps the social situation of the donor has changed in a way that may affect their candidacy or willingness to be a donor.

The physical examination includes measurement of vital signs and allows for confirmatory measurements

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

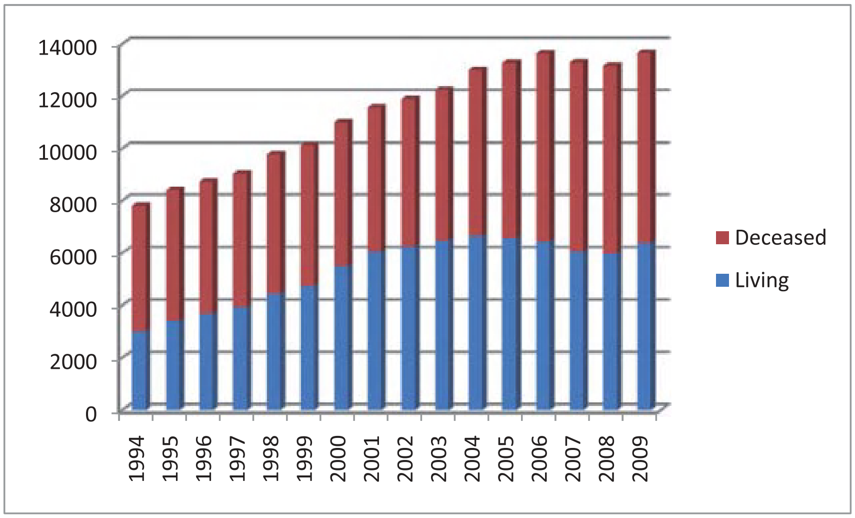

Figure 82.1 Number of living versus deceased kidney donors from 1994 to 2009.

of height and weight for the computation of the patient's body mass index (BMI). Particular attention is paid to the abdominal exam to evaluate the patient's body habitus and to document any prior surgical scars relevant to the surgical approach. This simple evaluation is essential to identify patients appropriate for minimally invasive donor surgery.

Donor anatomy is evaluated with multidetector computed tomographic (MDCT) angiography/urography with reconstructions. Multiphase MDCT images demonstrate the size of each kidney and the amount of renal parenchyma. Rapid symmetric uptake of intravenous contrast, combined with prompt excretion and drainage, documents the relative renal function and can obviate the need for routine renal scans. Donors found to have disparities in renal size, contrast uptake or excretion, or renal scarring are further studied with a MAG3 renal scan to ensure adequate renal function. The affected kidney is then chosen to ensure the donor is left with the highest functioning renal unit. Delayed urogram phases also document the anatomy of the collecting system of each kidney and ureter. Anomalies such as a partial or complete ureteral duplication could be missed without the urogram phase. Although uncommonly found, such anomalies could potentially alter the surgical approach. Incidental intra-abdominal pathology is often discovered at the time of MDCT imaging. Adrenal nodules are detected in a small proportion of patients and present a clinical challenge. If the adrenal lesions meet CT criteria for benign adenoma, and a functional metabolic work-up is negative, proceeding with donation is reasonable.

In one study, approximately 30% of kidneys evaluated using MDCT technology were found to have incidental renal pathology, such as low density lesions too small to characterize, renal cysts, and calyceal calcifications [2]. This relevant surgical information does not necessarily preclude donation. Reviewing over 850 laparoscopic and open donor nephrectomies from 2000 to 2007 at UCLA, approximately 19% of patients were found to have incidental renal findings, such as low density lesions considered "too small to characterize" on preoperative evaluation (unpublished data). Alternatively, large or complex renal cysts require attention and may necessitate removal of the affected kidney.

An increasing number of calyceal calcifications are identified with high-resolution CT-based imaging and there is no clear recommendation on how to treat these potential donors. Patients with a history of nephrolithiasis or those found to have bilateral, multiple unilateral, or large renal stones are generally not considered candidates for donor nephrectomy. In our experience, donor candidates found to have a single small asymptomatic calcification, particularly if they are older donors, undergo a thorough metabolic work-up. If no abnormalities are detected, it may be reasonable to proceed with donation with appropriate counseling, removing the affected kidney.

CT-based imaging can also supplement the patient selection process by elucidating the amount of retroperitoneal fat. The amount of perirenal fat and the distance the kidney lies from the psoas muscle are tools that can be used to select higher BMI donors who will still be amenable to a laparoscopic approach (Figure 82.2). The majority of transplant centers included in a recent survey were noted to have a donor BMI cut-off of 35, although surprisingly, 31% of those participating did not have a donor exclusion BMI [3]. This becomes particularly important in patients with complex vascular anatomy as the amount of perirenal fat can indicate a more challenging dissection, especially at the renal hilum. Vascular anatomy has become increasingly

Figure 82.2 (A–C) Examples of differing amounts of perirenal fat in three patients, all with a body mass index of 33.

relevant to the surgical evaluation with the increasing adoption of laparoscopic approaches to kidney donor surgery, and MDCT has demonstrated impressive sensitivity to identify small vascular structures [4, 5]. The increased resolution along with three-dimensional (3D) reconstructions (Figure 82.3) may in fact increase operative safety, as well as identify small capsular and polar arteries such that attempts can be made to preserve

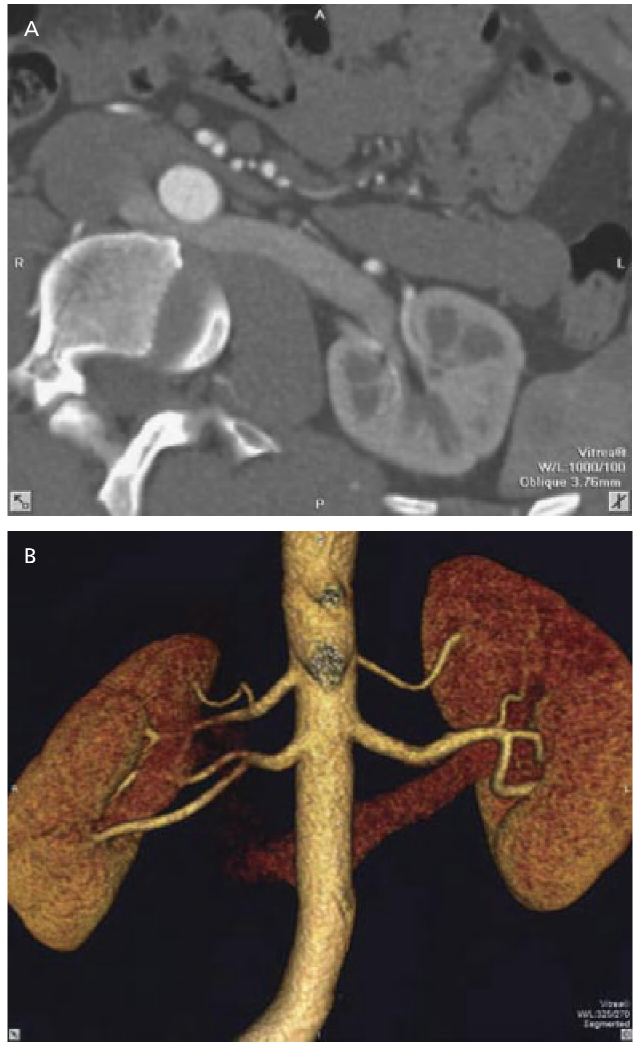

Figure 82.3 (A) MDCT showing a retroaortic vein. (B) 3D reconstruction of the same patient with a retroaortic vein and bilateral accessory upper pole arteries.

these structures if indicated (Figure 82.4). If there are two symmetric kidneys, the left kidney is traditionally preferred due to the longer renal vein length. A right nephrectomy may be preferred when the left kidney is found to have more than two arteries. However, depending on the institution, arterial anatomy that is complex should be reviewed on a case-dependent basis with the donor and transplant surgeons. Rarely has venous anatomy alone precluded a left-sided LLDN in our series.

Surgical risks

It is imperative to highlight possible complications to healthy donors when obtaining the informed consent. The possibility of open conversion, although low, is emphasized with every potential donor. The donor needs to understand the intraoperative risks, such as

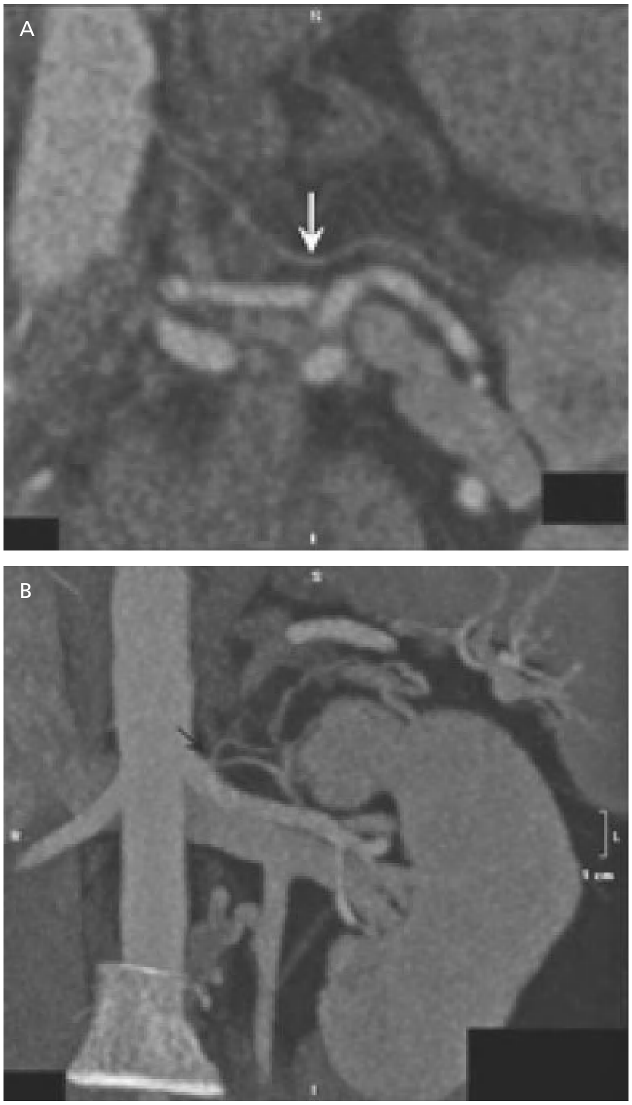

Figure 82.4 (A) 1-mm left upper pole accessory renal artery (arrow). (B) Single left renal artery with early bifurcation (arrow) of two small capsular arteries. (Reprinted with permission from the American Journal of Roentgenology.)

bleeding that could result in a transfusion; injury to organs such as bowel, colon, pancreas, adrenal gland, diaphragm, stomach, spleen, liver, such that repair or additional operations are needed; and other major complications such as deep vein thrombosis, myocardial infarction, stroke, and death. Additional complications, such as neuropathy, chylous ascites, hernia formation, pain, and wound complications, need to be discussed as well, so the donor has a realistic expectation of the postoperative course.

This direct discussion can reveal patients who are not or no longer willing to proceed. A medical alibi should be offered, to ensure that the patient does not feel undue pressure to proceed with the process that may have taken some time to complete. This offers an escape from donation while still maintaining the patient's status in the recipient's opinion.

Surgical technique

Regardless of the different approaches, the steps of the living donor nephrectomy should be similar. Although different techniques and approaches have been described, the transperitoneal approach is most often utilized [3]. After induction of general anesthesia and placement of a Foley catheter and orogastric tube, the patient is placed in a modified or near-flank position. Some flexion of the table is used without the kidney rest. The extremities and all pressure points are meticulously protected with pillows, and the patient is secured to the table with tape. For purely laparoscopic donation, the pubic area is also prepped into the field.

In case of a transperitoneal access, the pneumoperitoneum is obtained through a Veress needle puncture, an optical trocar access, or a Hasson technique. There is no clear advantage between access techniques and the access approach is largely surgeon dependent; however, the open approach (Hasson) has been reported to have fewer complications in select series [6–8]. The position of the trocars is operator dependent. A classical triangular diamond-shaped configuration with the camera port in the middle is the traditional teaching. Our technique utilizes a linear port configuration along the pararectal line, with the camera placed at the most cephalic position in order to obtain a better ergonomic position for the surgeon and camera holder (Figure 82.5).

After obtaining access, the procedure starts with mobilization of the colon. The colon is displaced medially by dissection along the line of Toldt and careful reflection of the colonic mesentery is performed. Care should be taken to not continue the dissection lateral to the kidney at this point. Most of this dissection can be done with a combination of sharp and blunt dissection with a scissor/ultrasonic shears and kittner/grasper. For a left-sided donor, the colon, pancreas, and spleen are mobilized to the level of the diaphragm. The liver is mobilized in an analogous manner for right-side donor surgeries as well as kocherizing the duodenum. The lateral attachments of the kidney are left in place to prevent the kidney from falling medially. Once the colon is completely mobilized, the upper pole of the kidney is dissected. In order to facilitate this part of the procedure, aggressive mobilization of the spleen is recommended as mentioned above (see Video 82.1). This is obtained by incising the posterior peritoneum to the level of the crus of the diaphragm. With complete reflection of the spleen and tail of the pancreas, the adrenal gland and renal vein are identified. It is helpful for the upper pole dissection to introduce a fourth trocar off the tip of the 11th or 12th rib to aid with lateral and downward retraction of the

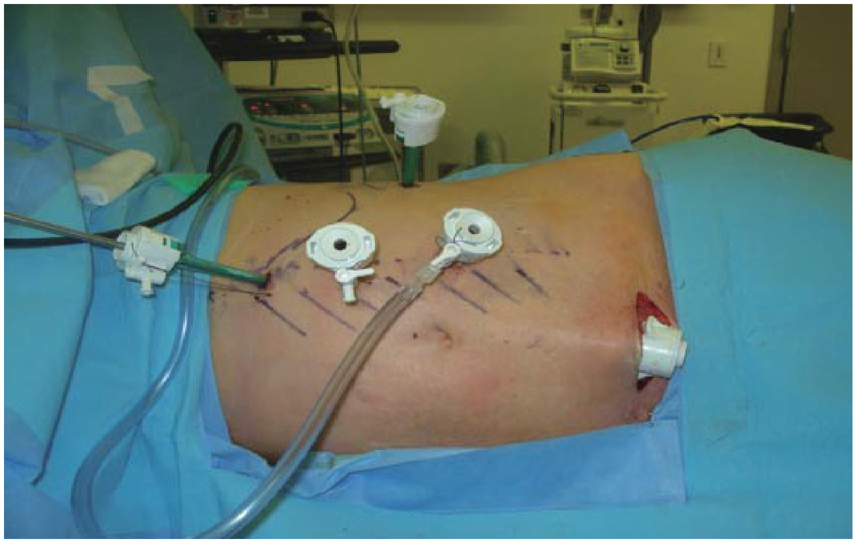

Figure 82.5 Patient positioned in operating room with four 5-mm ports with the camera most cephalad (left). A low transverse extraction site is shown with a 15-mm port in place.

kidney. Care is taken to do as little retraction as possible directly on the kidney, as the fat superior and/or lateral to the kidney can often be retracted without touching the organ. With inferior/lateral retraction on the kidney, the plane between the adrenal gland and the upper pole of the kidney is meticulously dissected to the renal hilum (see Video 82.2). During the adrenal dissection, care has to be taken to avoid small upper pole accessory arteries or capsular branches that may not have been previously detected by preoperative imaging.

Once the upper pole of the kidney has been isolated, attention is moved inferiorly to the identification of the gonadal vein and ureter. An alternative approach would be to start with the gonadal/ureter dissection before the upper pole. Although early data recommend transection of the gonadal vein *en bloc* with the ureter at the level of the iliac vessels [9–11], more recent studies have shown that the gonadal vein can be ligated safely 2–3 cm from the renal vein with dissection between the ureter and the gonadal vein itself (see Video 82.3) [12]. The advantages of this technique are believed to be improved elevation of the kidney and easier access to the lumbar vein. Whether the gonadal vein has been divided or not, the ureter is still elevated and dissected distally to the level of the iliac vessels. Care is taken to not strip the ureter, and division of attachments is recommended to be performed with bipolar energy, such as the ultrasonic shears. After completing the ureteral dissection, the ureter is then elevated along with the lower pole of the kidney with a blunt-tipped instrument all the way to the sidewall and dissection of the posterior attachments is bluntly performed. This helps with further elevation and exposure of the renal hilum. The dissection towards the renal hilum is typically medial to the gonadal vein stump and continued upwards to the level of the lumbar vein. If a lumbar vein is identified, it is clipped and transected. Alternatively, the lumbar vein can be stapled simultaneously with the renal artery. Meticulous dissection is than performed around the renal hilum and the renal artery is isolated and dissected to the level of the aorta. Depending on the donor anatomy, the adrenal vein is often divided if thought to significantly aid in length of the renal vein. If the lumbar or adrenal vein is clipped, care must be taken to avoid these clips when later stapling the renal vessels.

If a pure laparoscopic dissection, at this point the extraction site incision is made. This is typically a low-transverse (Pfannenstiel-like) incision approximately at the pubic hairline. If using a hand-assisted technique, this is often a midline or transverse incision near the umbilicus. Although some authors reported shorter warm ischemia time with the hand-assisted technique, others reported that short warm ischemia time can also be obtained with the pure laparoscopic technique as well, with better cosmetic results [13]. In case of a pure laparoscopic technique, after the Pfannenstiel incision has been obtained, the fascia is identified and a subcutaneous flap is created. A vertical midline incision is made in the fascia towards the umbilicus. A 15-mm trocar is inserted as close as possible to the umbilicus. Through this port the endovascular stapler may be used as well as placement of the 15-mm EndoCatch bag for organ extraction. For right-sided cases, our preference is to staple through the inferior pararectal trocar as this angle appears to be more aligned with the inferior vena cava (IVC). Once the extraction site is created, the lateral attachments of the kidney are divided. The kidney is fully elevated

with a “snake” liver retractor at the upper pole and a blunt instrument under the lower pole; this straightens the renal hilum to ensure adequate length of the vessels (see Video 82.4). The renal artery and vein are taken separately, as well as the ureter at the level of the iliac vessels with the endoscopic stapler (see Video 82.4). The organ is than placed into an endoscopic bag and extracted (see Video 82.5). Although some surgeons still prefer to ligate the artery and vein with Hem-o-lok clips, it has to be stressed that their use has been forbidden both by the Food and Drug Administration (www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfRes/res.cfm?ID=45876) and the manufacturer (www.teleflexmedical.com), since cases of dislodgement and subsequent death have been reported. Once removed, the kidney is immediately placed in ice slush and the artery flushed with cold irrigant of choice (e.g. Wisconsin’s solution, lactated Ringer’s with 5000 U of heparin, etc).

The fascia is closed in a running or interrupted fashion with figure-of-eight sutures per surgeon preference. If the patient is very thin, the knots are often buried. The abdomen is reinsufflated and full inspection, including of the staple lines, takes place. If there is clot or any concern for bleeding at this point, the pneumoperitoneum is decreased back to 5 mmHg and the abdomen further inspected. Our preference at this point is to place Surgicel along the adrenal dissection and area of renal hilar dissection. The ports are removed under direct vision and an attempt at suctioning out the insufflated abdomen is performed. Skin sites are then closed in a subcuticular fashion.

Postoperative care

The orogastric tube is removed prior to extubation. The postoperative management should include serial hematocrits for the first 24 h and as needed. We routinely check a hematocrit in recovery and in the morning. The Foley catheter should be removed early in the morning of postoperative day 1 unless there is a concern regarding urine output. It is advised that the patient starts ambulating as soon as possible, whether this is in the evening of surgery or first thing in the morning at the latest. Clear liquids may be given on the day of surgery and diet advanced on postoperative day 1. If ketorolac is used, there is often little need for additional narcotics in these patients. Consideration should be given to using acetaminophen to try and reduce narcotics to lessen postoperative ileus. It has been shown that the use of intravenous ketorolac 30 mg every 8 h for the first 24 h may reduce hospital stay without increasing the risk of bleeding or renal dysfunction [14]. If the patient responds well to the pain and there are no contraindications, the patient could be discharged from hospital on the first postoperative day. The patient is typically seen by the surgeon 7–14 days later for a regular check up. Normally, if the postoperative course has been regular, there is no need for laboratory tests at this time. It is recommended that the patient should be seen by their primary care physician and have a creatinine drawn and blood pressure checked within 3 months of surgery as a baseline. It is important to advise donors about avoiding nephrotoxic medications if possible, including nonsteroidal anti-inflammatory drugs (NSAIDs) on a chronic basis, since this may result in loss of kidney function. There are normally no other limitations for donors who can conduct a normal lifestyle without restrictions.

Outcomes and discussion

LLDN is now a universally accepted alternative to open donor nephrectomy. A recent meta-analysis as well as an OPTN database analysis concluded that both approaches for procurement have equal effectiveness [15, 16]. Moreover, potential benefits to the laparoscopic donor include decreased pain, shorter hospital stay, improved cosmesis, and faster convalescence, as has been shown with various laparoscopic surgeries.

Complications of LLDNs have been reported to range from 5% to 29%, and the open conversion rate is generally less than 2% in larger series [11, 17–24]. Major intraoperative complications, renovascular complications, and need for open conversion have been acceptably low in most large centers. This coupled with the noted postoperative advantages has justified the transition to laparoscopic procurement. In turn, the minimally invasive technique is thought to be a contributing factor of increased living donation since it became available.

Open conversions are rare but are often the result of renovascular complications. In a reported series of 600 LLDNs, there were eight renovascular incidents (1.3%), all but one of which required open conversion [20]. Similarly, 10 of 12 conversions in another donor series were due to vascular injuries [19]. One cause of this complication is secondary to stapler malfunctions. Although there was a stapler misfire in our series on an accessory artery (0.13%), we prefer this method for transecting the renal vessels [24]. In addition, the use of nonabsorbable polymer ligating clips (Hem-o-lok) on the renal artery in living donors is contraindicated [25]. Vascular injuries with the Veress needle during access are very uncommon as well; estimated to occur in around 0.1% [6]. Veress needle access is utilized in 75% of centers that employed the pure laparoscopic approach according to a survey [3]. In our experience, if difficulty is encountered upon insertion of the Veress needle, or in select obese patients or those with multiple prior incisions, direct entry with a visual trocar in a desufflated

abdomen is attempted. An alternative method would be an open or Hasson technique.

Two separate studies have evaluated the use of intraoperative systemic heparin given to the donor prior to renal artery ligation during LLDN [26, 27]. Although neither study was randomized, both concluded that this was not necessary and did not increase the risk of thrombosis in the graft. Further, it may increase the risk of intraoperative or early postoperative bleeding, and the use of protamine for reversal has the risk of stroke, pulmonary hypertension, and anaphylaxis. Even so, the use of heparin and protamine is still practiced in most centers according to a 2008 survey [3].

There has also been controversy as to when to perform right-sided LLDN and whether it should be done. Much of this stemmed from the concern for a shorter right renal vein and very early reports of increased recipient graft thrombosis [28]. In this series, three of eight right-sided LLDN patients experienced this complication and two of the three had a duplicated renal vein; since at this time MDCT has replaced angiography to better define venous anatomy. With better preoperative imaging and surgical modifications, there were no vascular complications in the next nine patients. An increased need for back-table reconstruction due to shorter right venous anatomy has also been reported [29]. An Endo-TA stapler may be used to increase renal vein length [30] as opposed to an Endo-GIA stapler, although a modified Endo-GIA has been described for this purpose [31]. With a known shorter right renal vein, equal outcomes between right- and left-sided procedures are reported, including a recent study that concluded that right LLDN is not only faster but safer [32].

Striving to minimize surgical complications and improve outcomes is intuitive and never truer than in the circumstances surrounding healthy organ donors. The use of ketorolac may be controversial in this population but it has been shown that its use in surgical patients as well as in donors decreases pain and narcotic requirement, and arguably speeds up the return of bowel function [14, 33]. This was previously reported to not have a significant impact on long-term renal function [33]. With less narcotic requirement and quicker return of bowel function, there is often a shorter hospital stay. In our experience, the use of ketorolac combined with minimally invasive donation has likely contributed to a median hospital stay of 1 day, with patients ambulating, passing flatus, and tolerating at least a liquid diet prior to discharge [24].

As the number of living donors has increased, along with the acceptance of less stringent inclusion criteria, there has been a renewed focus on donor safety, including long-term outcomes. Prior evidence is such that living kidney donors experience a similar survival as nondonors and do not have an increased risk of end-stage renal disease. Factors that have been associated with lower glomerular filtration rate after donation are age and being overweight, which are the same as in the nondonor population [34]. It has been estimated that after nephrectomy, donors may experience an elevation in blood pressure of approximately 5 mmHg 5–10 years postoperatively [35]. Even though the prevalence of hypertension is still lower than in the general population, without a comparative healthy control group it is unknown whether this is an increased risk. Further, in donors who do develop hypertension, it is unknown whether this would have occurred had they not donated. There has also been discussion regarding the psychologic status of donors postoperatively. Although mental health has been reported to decrease during the first year after surgery in some, the overall quality of life is reportedly higher than in the general population [35]. Establishing a donor registry would help follow these patients and better determine the true risks to potential donors, not only at the time of surgery but in the long term as well [24]. It should be emphasized that donors require lifetime follow-up to assess blood pressure, creatinine, and perhaps proteinuria, so abnormalities can be diagnosed early to prevent further complications.

Conclusions

Fifteen years have passed since the first LLDN and this technique is firmly ingrained in most major transplant centers. Because of the proven safety, equivalent outcomes, and stated benefits, it is considered the standard of care at many institutions.

CHAPTER 83
Renal Surgery for Malignant Disease: Radical Nephrectomy and Nephroureterectomy

Ben R. McHone,[1] Thomas W. Jarrett[2] & Peter A. Pinto[1]

[1]Urologic Oncology Branch, National Cancer Institute, Bethesda, MD, USA

[2]Department of Urology, The George Washington University, Washington, DC, USA

Introduction

Laparoscopic radical nephrectomy (LRN) was introduced in 1991 by Clayman *et al.* [1]. This was a pure laparoscopic transperitoneal approach. Since its inception, modifications have been made to the LRN, including hand-assisted as well as the retroperitoneal approach [2, 3]. Although laparoscopic techniques have evolved, allowing urologic surgeons to perform minimally invasive partial nephrectomies for smaller renal masses, the LRN remains the gold standard for clinically localized, T2 renal masses. Additionally, some evidence suggests an advantage to radical nephrectomy in the presence of metastatic disease for cytoreductive purposes [4]. Furthermore, laparoscopic techniques have extended into the realm of treating upper tract urothelial carcinoma requiring nephroureterectomy. Now in the era of robot-assisted laparoscopic surgery, urologic surgeons are incorporating this technique for nephrectomy and nephroureterectomy. This chapter will review the indications, techniques, and results for laparoscopic and robotic radical nephrectomy and nephroureterectomy.

Indications/contraindications for nephrectomy

Indications for the use of LRN or robot-assisted laparoscopic radical nephrectomy (RLRN) include clinically localized T2 or T3 disease. Whenever possible, T1a renal masses are removed through the use of a partial nephrectomy [5]. The increased risk of cardiovascular mortality associated with decreased glomerular filtration rate (GFR) has been well documented [6]. This reduction in GFR has also been demonstrated in those who undergo radical nephrectomy for T1b lesions when compared to those who undergo partial nephrectomy [7]. Decreasing the risks associated with a compromised GFR, coupled with the sound oncologic data for nephron-sparing surgery, has led to the recommendation for partial nephrectomy for complex or T1b renal masses [8, 9]. If not amenable to minimally invasive techniques, then an open partial nephrectomy should be considered. Finally, LRN or RLRN may also be used in the setting of a cytoreductive nephrectomy in order to reduce the overall tumor burden when the metastatic disease burden is smaller in size than tumor burden within the kidney [4].

General contraindications are the same as for open radical nephrectomy. These include significant coagulopathy or comorbidities that preclude the patient from undergoing general anesthesia. Reports have been published regarding the minimally invasive management of a renal vein thrombus, but this is limited to highly experienced centers [10]. Previous abdominal surgery has not demonstrated an increased risk of either complications or need for conversion. Although previous surgery at the same site has demonstrated increased operative time and hospital stay, it is not a contraindication to performing laparoscopy [11].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Preoperative evaluation and patient preparation

The preoperative work-up for a patient with a renal mass is no different for a LRN from that for an open radical nephrectomy. This includes a detailed history and physical examination, a complete blood count, serum electrolytes, coagulation panel, calcium, and alkaline phosphatase. A chest X-ray or chest computed tomography (CT) scan is required to screen for pulmonary metastases. A bone scan is unnecessary in the absence of bone pain or an elevated alkaline phosphatase. If the serum creatinine is elevated, a 24-h urine creatinine level and possibly a MAG-3 or DMSA renal scan may be needed to assess contralateral renal function. Usually the patient presents with abdominal imaging demonstrating a renal mass. If abdominal imaging is inadequate, a three-phase CT or magnetic resonance imaging (MRI) is required to document enhancement of the renal mass. Abdominal imaging may aid in hilar dissection by preoperatively identifying multiple renal arteries or adherent anatomy. If there is concern for a renal vein or caval thrombus, a MR venogram should be obtained. Finally, although lymphadenectomy for renal cell carcinoma remains controversial, careful attention should be paid on imaging to regional and retroperitoneal lymphadenopathy. Despite the European Organization for Research and Treatment of Cancer (EORTC) trial demonstrating no improvement in survival in those who underwent lymphadenectomy for localized renal cell carcinoma [12], others have demonstrated improved staging capability [13] and, in certain situations, improved survival with lymph node dissection for clinically detected lymphadenopathy [14].

The patient is kept nil by mouth after midnight the evening before surgery. The use of a mechanical bowel preparation is optional. Some prefer to use a bowel preparation in order to decompress the colon and small bowel for improved visualization and working space within the abdomen. A single dose of an antibiotic agent is given 30 min prior to the first incision to cover skin flora. Sequential compression devices are placed on the calves of the patient and initiated prior to the induction of general anesthesia, along with an optional dose of subcutaneous heparin.

Laparoscopic transperitoneal nephrectomy

Patient positioning

The patient is initially placed in the supine position upon arrival in the operating room. After induction of general endotracheal anesthesia, an orogastric tube and bladder catheter are placed. The location of the extraction site, usually an infraumbilical Pfannenstiel incision, is marked on the patient's skin to ensure a straight incision after the patient is positioned. The patient is then carefully placed in a modified lateral decubitus position, angled at approximately 30º from the ground. The patient's flank overlays the kidney rest, an axillary role is placed, and an additional roll is placed longitudinally along the patient's back to support the thoracic and lumbar spine. Both legs are kept straight with a pillow or other padding placed behind the knees for support. Thick tape is used to secure the patient to the table at several points in order to prevent sliding during the procedure should the table require rotating (Figure 83.1). Finally, the abdomen is prepped sterilely, along with the corresponding flank in case of a need to convert to an open procedure.

Access

The abdomen is insufflated to a pressure of 15–20 mmHg utilizing a Veress needle. Once sufficiently insufflated, a 12-mm dilating trocar is placed with the use of a 0º lens to guide its position into the abdomen at the level of the umbilicus. The 0º lens is exchanged for a 30º 10-mm laparoscopic lens, and the abdominal contents are inspected for any injury from either the Veress needle or the first trocar. The Hasson approach to abdominal entry can be used, depending on surgeon comfort. This may be useful in the case of previous abdominal surgeries, though the utilization of Veress needle access is documented to be safe in this patient group as well [15]. A second 12-mm trocar is placed at the level of the umbilicus in the anterior clavicular line. A third, 5-mm trocar is placed approximately 8 cm cephalad to the umbilical trocar in the midline. For a right nephrectomy, an additional 5-mm port may be placed inferior to the subxiphoid process in order to assist with liver retraction. If the patient's abdomen is particularly obese, all respective port positions may need to be placed laterally in order to account for abdominal wall distortion. Furthermore, for particularly large renal masses, all 12-mm ports should be used to allow for maximum versatility in passing a greater variety of instruments through any port location. Finally, if an additional port is needed for retraction, an ideal placement is in the previously marked Pfannenstiel incision line. At the completion of the case, the extra port incision is extended and used to extract the specimen.

Procedure

Depending on the side of the procedure, the white line of Toldt is incised sharply without electrocautery, thus eliminating the risk of bowel injury due to thermal

Figure 83.1 Patient position for a transperitoneal laparoscopic or robotic-assisted radical nephrectomy.

spread. A plane is developed between the posterior mesenteric and anterior perirenal fat using a combination of blunt and sharp dissection. The respective colon is mobilized medially from the iliac vessels to the respective hepatic or splenic flexure.

For a right nephrectomy, the hepatic flexure is released by dividing the renocolic ligament. This allows for further medial mobilization of the colon. The duodenum is mobilized using sharp dissection. Minimal use of blunt dissection is encouraged around the duodenum to avoid inadvertent serosal injuries. Duodenal mobilization is completed after gaining adequate exposure to the inferior vena cava (IVC) (also referred to as a Kocher maneuver).

The left colon, in the case of a left nephrectomy, is mobilized similarly with a combination of blunt and sharp dissection. The splenorenal ligament and splenophrenic attachments are divided in order to mobilize the spleen medially, *en bloc* with the splenic flexure, which provides medial reflection of the tail of the pancreas. This maneuver is important to minimize the risk of injury to the tail of the pancreas during left hilar dissection. Complete splenic mobilization often requires visualizing the stomach above the spleen. Finally, mobilization of the left colon is complete once the aorta is exposed.

Once Gerota's fascia is exposed, the psoas is identified, anterior to which is the ureter. Alternatively, the mid ureter can be found posterior and medial to the gonadal vein. This relationship is particularly important when tracing the ureter to the renal hilum in the case of a right nephrectomy. Care is taken to sweep the gonadal vein medially, separating it from the ureter and avoiding the risk for avulsing it from the vena cava. The ureter is kept intact, which allows it to be used as a handle for anterior and cephalad retraction of the kidney later in the case.

At this point the lower pole of the kidney is mobilized within Gerota's fascia. This has the potential for causing significant bleeding in the case of large, lower pole masses or if multiple parasitic vessels are encountered. To help facilitate lower pole mobilization with adequate hemostasis, electrocautery, any of a number of ultrasound-based coagulation devices, or the LigaSure (Valleylab, Boulder, CO, USA), which uses an electrical current to fuse blood vessels, may be utilized. Prior to the start of dissection, we recommend placing a small lap pad into the patient. In the event of unexpected bleeding, this can be used to improve visualization, or in the worst case, tamponade bleeding to allow time for open conversion.

With the lower pole of the kidney mobilized, the ureter can be traced cephalad to the renal hilum. Care needs to be taken when dissecting toward the renal hilum in the event of a lower pole accessory vessel. Retracting anteriorly and cephalad on the kidney allows for better exposure to the renal vein and artery. Judicious use of energy-based dissection may be required to divide the fibrous lymphatic tissue often surrounding the renal artery.

For a left nephrectomy, ensuring the left renal artery is positioned posterior to the exposed renal vein ensures

that the superior mesenteric artery is not mistaken for the left renal artery. Next, when the left renal vein is isolated, the gonadal vein can be clipped and divided if necessary. Caution should be exercised at this point to prevent avulsing a potential lumbar vein that can feed into the posterior surface of the left renal vein. If the adrenal gland is to be taken, the left adrenal vein can be clipped and divided at this point. Once the renal artery and vein are isolated, an endovascular stapler or clips are used to secure the artery and vein. Once the artery has been divided, if the renal vein does not decompress as expected, thus raising the concern for a renal vein thrombus, or if there is a known renal vein thrombus preoperatively, laparoscopic ultrasound is employed to ensure the thrombus has retracted completely before dividing the vein.

After the artery, followed by the vein, has been divided, the decision is made whether to preserve the adrenal gland or to take it with the specimen. For large, central tumors or those located in the upper pole of the kidney, removing the adrenal gland with the kidney should be performed in order to ensure there are negative margins. In the case of a right nephrectomy, moving superiorly along the IVC will expose the short, right adrenal vein. Care should be taken as this is a delicate vein and avulsing it can lead to significant hemorrhage. Once divided, using energy-based dissection can facilitate expeditious mobilization of the kidney and adrenal gland from the surrounding renal fossa, while also securing potential parasitic vessels feeding the tumor. Care is taken superiorly to avoid inadvertent injury to the diaphragm. Also, at this point, the ureter is clipped and divided, completely freeing the specimen. When taking the left adrenal gland, either the left renal vein can be stapled proximal to the insertion of the adrenal vein, or the adrenal vein can be clipped and divided separately.

In the case of an adrenal-sparing nephrectomy, energy-based dissection can be used to effectively dissect and coagulate any small feeding vessels between the kidney and the adrenal gland.

Current evidence does not suggest a benefit to performing a lymph node dissection for T1 or T2 disease in the absence of clinically positive nodes [12, 16]. However, retrospective data do suggest some benefit to improved staging in those with clinically detected nodal disease [13]. Adding to the argument in favor of extended lymphadenectomy are data from Pantuck *et al*., who demonstrated improved survival in those patients with metastatic disease who underwent cytoreductive nephrectomy and lymphadenectomy prior to immunotherapy compared to those who did not receive an extended lymphadenectomy [14]. Depending on the clinical situation and surgeon preference, the lymph node dissection can be performed either laparoscopically or robotically, and is not precluded based on a minimally invasive approach.

Finally, the specimen is entrapped in any commercially available laparoscopic organ retrieval device. The specimen, depending on the size of the tumor, can be removed through a small extension of either the lateral or umbilical trocar incisions, or through a separate, cosmetically preferable, Pfannenstiel incision. Another option for specimen extraction is through morcellation. Though not commonly performed, it provides for a smaller incision compared to the larger Pfannenstiel incision for whole-specimen extraction [17].

Laparoscopic retroperitoneal radical nephrectomy

Advantages/disadvantages

The retroperitoneal approach to an LRN can be advantageous in cases where the patient has had prior abdominal surgeries. However, if the patient is particularly obese or has a large amount of retroperitoneal adipose tissue, proper orientation can be difficult. Improper orientation and loss of appropriate landmarks can lead to significant operative challenges and even inadvertent caval transaction when mistaken for the renal vein [18]. Furthermore, previous renal surgeries or renal infections can lead to significant perirenal adhesions, thus adding additional difficulty to the retroperitoneal approach. Finally, large renal masses with multiple parasitic vessels or those that may involve other organs should not be removed retroperitoneally.

Positioning

The patient is placed in the full flank position. After the axillary roll and appropriate anterior/posterior bolsters are placed, the patient is secured with thick tape to the bed. The table is flexed to extend the space between the 12th rib and the iliac crest.

Procedure

After being prepped and draped sterilely, an incision is made off the tip of the 12th rib large enough to accommodate the surgeon's index finger. With the oblique muscles divided, the lumbodorsal fascia is incised and the retroperitoneum is entered. The surgeon's index finger is inserted into the retroperitoneum, and the psoas muscle and lower pole of the kidney are palpated (Figure 83.2). A commercially available balloon dilator that accommodates a 10-mm laparoscopic lens is inserted into the incision under direct vision. The potential retroperitoneal space is opened with the dilating balloon to a volume of approximately 800 mL (Figure 83.3). After

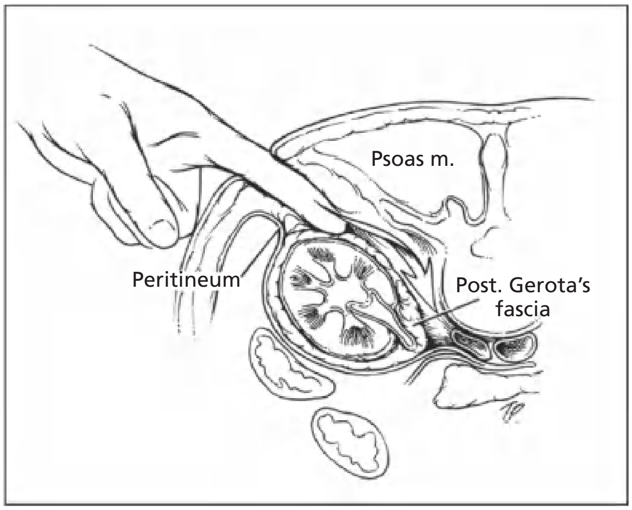

Figure 83.2 Palpation of the retroperitoneum prior to balloon dilator placement (reproduced from Pinto, P.A., Jarrett, T.W. Renal surgery in adults. In: *Retroperitoneoscopy and Extraperitoneal Laparoscopy in Pediatric and Adult Urology*. New York, Springer, 2003, with permission).

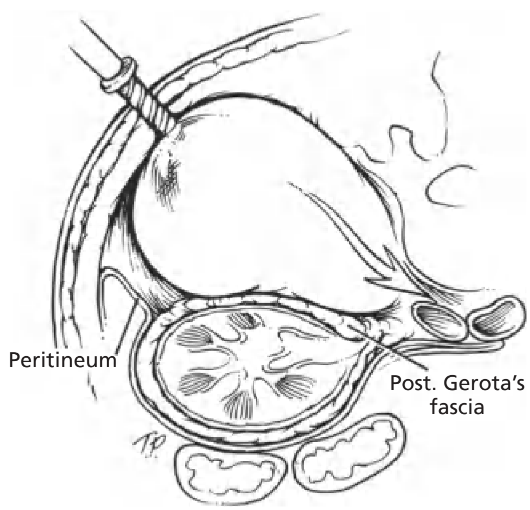

Figure 83.3 Creation of the working space with a balloon dilator in the retroperitoneum (courtesy of P. A. Pinto and T. W. Jarrett).

deflating and removing the balloon, a blunt-tipped trocar with a soft collar is placed into the incision. The soft collar on the inside of the incision helps maintain insufflation as well as prevent subcutaneous emphysema. Furthermore, this port does not project far into the working space, therefore not impairing the view of the kidney. The laparoscope is placed through this trocar.

Two additional trocars are placed. A 12-mm trocar is placed lateral to the camera port and approximately

Figure 83.4 Patient position with ribs and port placements marked.

2 cm cephalad to the iliac crest. A second 5-mm trocar is placed off the tip of the 11th rib (Figure 83.4). Finally, an optional additional 5-mm port can be placed off the tip of the 10th rib. When placing the ports medial to the initial camera port, the peritoneal lining must be swept medially or inadvertent peritoneal entry and bowel injury may occur.

After the 10-mm 30º lens is placed through the 12-mm inferior port, surgical orientation is achieved based upon the position of the psoas muscle and overlying ureter. At this point, the psoas muscle and tendon are dissected free of all retroperitoneal fat. Anterior and medial to the tendon will be the ureter. As with the transperitoneal approach, the ureter is traced back to the renal hilum and is used for placing traction on the kidney and hilum. Care is taken at this point as the IVC (for a right nephrectomy) or the aorta (for a left nephrectomy) is medial and in close proximity to the ureter.

For a left nephrectomy, as the ureter is traced to the renal hilum, dissection should be performed bluntly with the irrigator–aspirator in case an ascending lumbar vein is encountered entering the renal vein. If found, the vein is clipped and divided before proceeding to the renal hilum.

The ureter is traced superiorly along the medial aspect of the psoas muscle. This helps to keep the dissection in proper orientation and posterior to the kidney. The renal hilum is identified based on pulsation of the renal artery. Gerota's fascia is incised over the pulsation to expose the renal artery and vein. The artery and vein are isolated and divided as described for the transperitoneal approach.

After the kidney has been completely freed from the renal fossa and the ureter divided, the kidney is placed in a laparoscopically-deployed organ entrapment device. If the mass and kidney are small, the initial port can be extended in order to deliver the kidney. In cases

where the specimen is prohibitively large, a Pfannenstiel incision is made and the space of Retzius is entered. Matin and Gill described a modified Pfannenstiel incision that is lateralized to the side of the surgery [19]. Dissection is carried down to the anterior rectus fascia and a vertical incision is created along the lateral rectus border. With the fascia and rectus muscle retracted, the transversalis fascia is divided near the pubis and the extraperitoneal space is entered. Careful blunt dissection into the retroperitoneum through the Pfannenstiel incision can allow for delivery of larger specimens through a lower abdominal incision [19].

Hand-Assisted laparoscopic nephrectomy

Advantages/disadvantages

There are several advantages to the use of hand-assisted laparoscopic nephrectomy (HALN). It is often helpful for those with little experience with laparoscopic surgery and thus can help serve as a bridge between the open and pure laparoscopic approaches. It is particularly helpful when large renal masses are encountered and there is significant risk for intraoperative bleeding. HALN also allows for the use of tactile sensation, which is useful in cases where the anatomy is obscured. Finally, it may also be used as a technique to convert from a pure laparoscopic approach. One disadvantage of this approach is that it often results in a cosmetically suboptimal incision compared to the Pfannenstiel incision when used for specimen extraction. Additionally, maintaining adequate pneumoperitoneum, and thus proper visualization, can be difficult if the hand port leaks or if the incision for the port is too long.

Position and trocar placement

Patient position is the same as for the laparoscopic approach. The details of trocar placement and nuances of various hand ports are beyond the scope of this chapter. Briefly, three major hand-port systems are commercially available. The LapDisc™ (Ethicon Endo-Surgery, Cincinnati, OH, USA) is a one-piece system that is quickly inserted into an abdominal incision the length of the surgeon's glove size. Although the LapDisc™ occupies the smallest amount of external surface area on the abdomen, each time the hand is removed, the port must be untwisted and thus the pneumoperitoneum is lost. The GelPort™ (Applied Medical, Rancho Santa Margarita, CA, USA) consists of a larger diameter system through which the surgeon can place their hand through a gel-like material into the abdomen. This outer gel sealant allows for the maintenance of the pneumoperitoneum despite the surgeon moving their hand in and out of the abdomen. The drawback of the GelPort™, however, is that it takes up a larger amount of surface area on the external abdomen and may interfere with other ports. Finally, the Omniport™ (Advanced Surgical Concepts, Wicklow, Ireland) is a cuff system that is placed through the skin incision, into the abdomen, and is inflated with a separate pump once the surgeon's hand is placed through it. The advantage of the Omniport™ is that it compensates for an excessively large incision, thus preventing leakage of the pneumoperitoneum around the port. However, each time the surgeon's hand is removed, the cuff needs to be deflated and the pneumoperitoneum is lost [20].

For a right nephrectomy, the hand port is placed in the right lower quadrant, a 12-mm trocar at the umbilicus, another 12-mm camera port in the midline approximately 8 cm cephalad to the umbilicus, and a 3- or 5-mm port immediately inferior to the subxiphoid process for a liver retractor (Figure 83.5A). For a left nephrectomy, the hand port is placed immediately below the umbilicus in the midline, followed by a 12-mm trocar 8–10 cm lateral to and at the level of the umbilicus. Finally, a third 12-mm port is placed 8 cm cephalad to the umbilicus for the camera (Figure 83.5B).

Procedure

The white line of Toldt is incised sharply while the nondominant hand through the hand port places traction on the colon medially. After the correct plane between the colonic mesentery and Gerota's fascia is entered, the colon is swept medially with the nondominant hand and the irrigator–aspirator.

For a right nephrectomy, the renocolic ligament is divided while the nondominant hand retracts the flexure medially. This exposes the duodenum and Gerota's fascia. As with the pure laparoscopic approach, the duodenum is reflected sharply. At this point, a liver retractor is placed through the subxiphoid port to elevate the liver and allow better access to the renal hilum.

For a left nephrectomy, the splenorenal and splenophrenic ligaments are divided. The hand provides gentle medial traction on the spleen to allow for exposure to the upper pole.

The psoas muscle is identified and the ureter and gonadal vessels are isolated. For a right nephrectomy, the ureter is retracted anteriorly with the hand while the gonadal vessels are swept medially with the irrigator–aspirator. On the left, the vessels are taken with the ureter. The ureter is then traced toward the renal hilum. At this point, the lower pole of the kidney is mobilized and retracted anteriorly and cephalad with the hand, while the renal vessels are dissected free with a combination of the irrigator–aspirator and energy-based dissection. In cases where a large renal mass partially

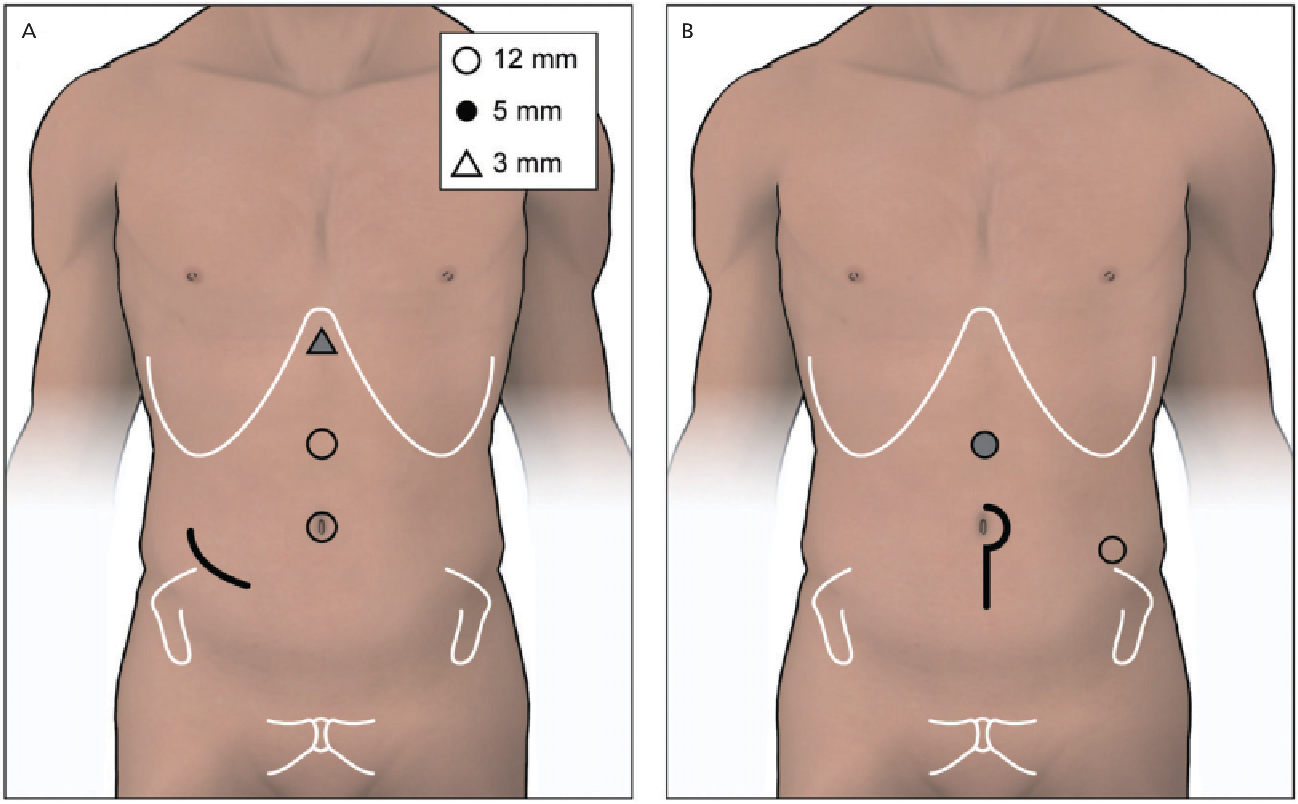

Figure 83.5 (A) Port placement for a right nephrectomy. The hand-port is indicated by the solid line. (B) Port placement for a left nephrectomy. The hand-port is indicated by the solid line.

obscures the renal hilum, the surgeon's use of their index finger can assist by palpating the renal artery. After sufficient exposure of the vein and artery is achieved, the endovascular stapler or clips are used to divide the artery, followed by the vein, while maintaining exposure of the renal hilum with the surgeon's hand.

At this point, the decision must be made whether to keep the adrenal or remove it with the kidney. On the right side, if the adrenal gland is to be taken with the kidney, the nondominant hand is used to retract the kidney laterally while the irrigator–aspirator is used to bluntly dissect the adrenal vein. After the short adrenal vein is exposed, it can be clipped and divided sharply. Once divided, a combination of energy-based dissection and finger-fracturing of the surrounding renal attachments expeditiously mobilizes the kidney and adrenal gland. While doing this, the surgeon is also simultaneously palpating and securing parasitic vessels feeding the tumor. Finally, the ureter is ligated and divided, completely freeing the specimen.

If there is adequate distance between the adrenal and renal mass, then salvage of the adrenal gland is appropriate. Dissection of the adrenal is performed by retraction on the adrenal with the off-hand and division of the adrenal gland from the kidney with energy-based dissection. The remaining portion of the nephrectomy is completed as described in the above section.

Finally, we recommend the use of a laparoscopically-deployed entrapment device for HALN. This helps protect the exposed incision from the unnecessary risk of tumor implantation.

Robot-assisted laparoscopic radical nephrectomy

Advantages/disadvantages

RLRN allows urologic surgeons with minimal laparoscopic skills to more easily transition open surgical techniques into a minimally invasive procedure. Disadvantages of this procedure include the lack of a haptic interface and the increased operating room costs imposed when using the robotic approach. Furthermore, operative time may be increased as a result of docking and undocking the robot [21]. Yet as robot-assisted surgery becomes more commonplace in urologic training programs, the role of RLRN will continue to expand. The following will describe the use of the da Vinci robotic system (Intuitive Surgical Inc., Sunnyvale, CA, USA) for a radical nephrectomy.

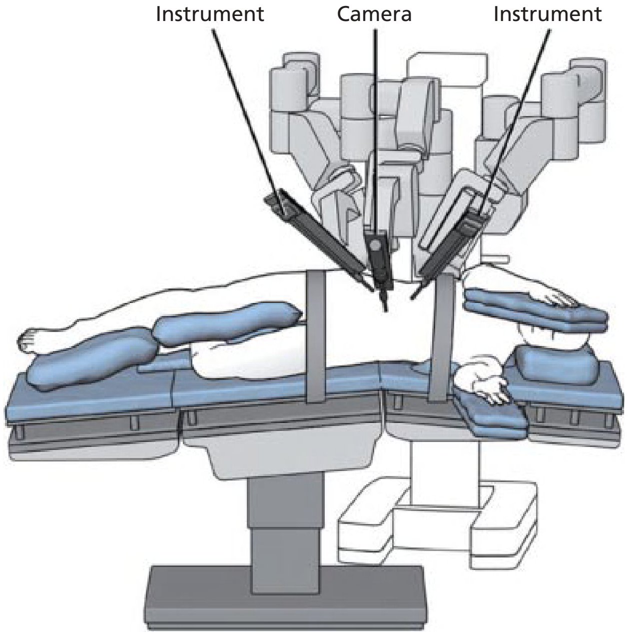

Figure 83.6 Robot docking position for a transperitoneal nephrectomy.

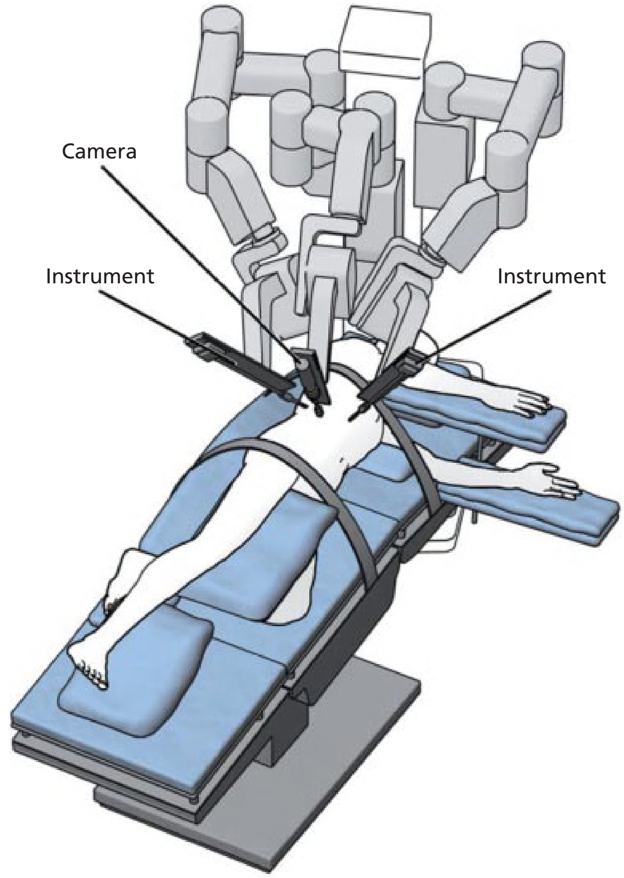

Figure 83.7 Robot docking position for a retroperitoneal nephrectomy.

Positioning

Robotic renal surgery can be performed both transperitoneally and retroperitoneally. For a transperitoneal approach, the robot is docked from the back of the patient at a 20° angle toward the head of the patient (Figure 83.6). When performing retroperitoneal robotic renal surgery, the robot is docked directly over the head of the patient (Figure 83.7). The patient is positioned in the modified lateral decubitus position as previously described for the transperitoneal approach with attention being paid to the arm ipsilateral to the affected kidney. If this arm is not positioned medial and cephalad, it could limit the movement of the subcostal robotic instrument.

Procedure

With the patient properly positioned, a pneumoperitoneum is achieved to a pressure of 15–20 mmHg. A 12-mm umbilical trocar is placed and the abdominal contents are inspected for adhesions and to rule out bowel injury after establishment of pneumoperitoneum. Two additional 8-mm robotic trocars are placed, each 8 cm from the umbilical trocar and from each other. A 12-mm assistant trocar is placed approximately 8 cm inferior to the umbilical trocar. An additional 5-mm assistant trocar is placed superior to the umbilical port if needed for organ retraction. When using the standard system, the trocars need to be spaced out further to avoid robotic arm collisions. When using the S or Si systems, the slimmer profile of the robot allows the trocars to be placed in closer proximity to each other.

Using the robotic Maryland forceps and electrocautery shears, the white line of Toldt is identified and incised sharply while the assistant is retracting medially on the bowel. Once the proper plane between the mesocolon and Gerota's fascia is established, much of the bowel mobilization can be done bluntly.

After adequate bowel mobilization, the ureter and gonadal vessels are exposed and lifted anteriorly to expose the psoas muscle. The assistant may retract anteriorly on the ureter, allowing the robotic surgeon use of both hands for additional dissection. For a right nephrectomy, the gonadal vessel needs to be swept medially in order to prevent inadvertent injury to or avulsion of the gonadal vein. Blunt dissection using both robotic arms for traction–counter-traction sweeping movements is performed when progressing cephalad along the psoas toward the hilum.

For a left nephrectomy, the spleen is mobilized as described for the pure laparoscopic approach. In the case of a right nephrectomy, the Kocher maneuver is performed exclusively with sharp dissection in the same manner as previously described.

With the lateral attachments of the kidney left in place, exposure of the hilum and renal vasculature can proceed. The Maryland dissector is used to retract the kidney laterally to place mild traction on the hilum for dissection. The bedside assistant may also be utilized for this. Electrocautery is often required to divide the dense lymphatic and fibrous tissue surrounding the renal artery. For large renal masses on the right, the robot may be helpful in dissecting an obscured renal artery from an interaortocaval approach. After the renal vasculature has been sufficiently exposed, the assistant inserts an endovascular stapler to divide the artery, followed by the renal vein. Alternatively, the assistant can ligate the vessels with clips. In addition, the robotic system allows the console surgeon to apply locking clips if the bedside assistant is unable to.

With the renal vasculature divided, an adrenal-sparing nephrectomy may be performed based on the location of the renal mass. After the kidney has been fully mobilized medially, it is freed from the surrounding renal fossa. At this point, liberal used of electrocautery and bipolar energy through the Maryland forceps can help minimize bleeding from parasitic vessels. Finally, with the kidney completely free within the abdomen, the pneumoperitoneum is slowly dropped and the renal fossa observed for several minutes to inspect for bleeding. The robot is undocked and the specimen is removed through an extraction site that was marked previously on the patient.

Laparoscopic, hand-assisted or robot-assisted nephroureterectomy

The indication for a nephroureterectomy is high-grade invasive urothelial carcinoma of the renal pelvis, proximal or mid ureter. The nephrectomy and proximal ureteral mobilization for a nephroureterectomy, regardless of the approach, are performed with the same positioning and port placement as for a radical nephrectomy. For a hand-assisted approach, an additional 12-mm port may be placed in either the right or left lower quadrant to aid in distal ureteral dissection. All specimens should be removed from the abdomen via an organ entrapment device and careful attention should be paid not to enter the collecting system during the laparoscopic part of the procedure due to the risk for tumor seeding [22]. Here we will review the various techniques for managing the distal ureterectomy and bladder-cuff excision.

Open technique

The open technique for distal ureterectomy allows the surgeon to offer the patient a minimally invasive nephrectomy and one incision to extract the specimen and manage the bladder cuff. The location of the incision is dependent on the technique used to perform the nephrectomy. Once the bladder is exposed and the anterior cystotomy is created, the ureteral orifice can be carefully excised. Suturing to close the orifice can help provide a handle for manipulating the intramural ureter during its dissection. Once excised, the specimen is removed *en bloc* and both cystotomies are closed. This approach to managing the bladder cuff is particularly useful in those patients with distal ureteral tumors in whom it is critical to have sufficient bladder-cuff excision [23].

For the hand-assisted approach, the distal ureterectomy can be completed using the incision for the hand port. If the hand port was placed in the midline, the incision may need to be extended inferiorly to gain adequate exposure of the bladder and ureteral orifice. Use of a Gibson incision for the hand port may obviate the need for a larger cystotomy as the bladder cuff may be excised extravesically. In this case, the ureter is dissected down to its intramural segment and the entire ureter and orifice are completely excised through a posterolateral cystotomy.

Transurethral excision of the ureteral orifice

When a transurethral excision is performed prior to the nephrectomy, the patient is positioned initially in the dorsal lithotomy position. A resectoscope and Collins knife are used to excise the ureteral orifice, essentially disengaging it from the bladder to allow for an easier distal ureterectomy without entering the bladder. Once completed, the patient is repositioned for the nephrectomy and ureterectomy part of the procedure. Some have reported higher rates of recurrence with this approach as the perivesical space is potentially exposed to tumor seeding through urine from the cystotomy [24]. In response to this concern, resection of the ureteral orifice *after* the nephrectomy and ureterectomy parts of the procedure have been completed has been proposed. This decreases the risk of potential tumor seeding from the upper tract after excision of the ureteral orifice [25].

Cystoscopically-guided transvesical bladder-cuff excision

In 1999, Gill *et al*. described a technique in which two 2-mm needlescopic ports are placed transvesically. The port ipsilateral to the affected side is used to place an endoloop around the ureteral orifice. Using a rigid cystoscope, a ureteral catheter is placed through the lumen of the endoloop and into the ureteral orifice. The cystoscope is removed and replaced with a resectoscope fitted with a Collins knife. The ureteral orifice and the intramural ureter are excised with the assistance of the contralateral needlescopic port. Once the bladder cuff is

completely excised, the endoloop is tightened around the ureteral orifice while simultaneously withdrawing the ureteral catheter. At this point, the patient is repositioned for the nephroureterectomy [26].

Stapling of the distal ureter

For the distal ureter, after the nephrectomy, the patient is placed in the steep Trendelenburg position to allow improved exposure to the bladder. With the ureter dissected to the ureterovesical junction, an endoscopic stapling device with articulating head is placed across the distal ureter with a portion of the bladder incorporated within the jaws of the device [27]. After the intra-abdominal part of the procedure is complete, the specimen can be extracted, the trocar sites closed, and the patient repositioned in the dorsal lithotomy position. Using a rigid cystoscope, a ureteral catheter is placed into the ureteral orifice and advanced until resistance is met. A resectoscope fitted with a Collins knife is used to incise the roof of the intramural ureter over the ureteral catheter. Once the intramural ureter is exposed, a resectoscope and roller-ball are used to fulgurate the mucosa of the exposed ureteral tunnel. Although some concern has been raised regarding encrustation of the exposed staple line within the bladder, this has not been born out in the literature [28]. Others have suggested that laparoscopic stapling of the distal ureter and bladder cuff may lead to increased recurrence rates due to unrecognized tumor entrapped within the staple line. Matin and Gill demonstrated an increased local recurrence rate and decreased survival in those who underwent laparoscopic stapling with cystoscopic unroofing and fulguration of the distal ureter [29]. To address the issue of retained urothelium within the staple line, a pure laparoscopic approach has been described where the distal ureterectomy and cuff excision are performed extravesically. Complete laparoscopic distal ureter and bladder-cuff excision has the advantage of not requiring repositioning of the patient for cystoscopy. Once the entire intramural ureter is freed from the bladder, a tissue-loaded endoscopic stapler is used to excise the distal ureter, ureteral orifice, and bladder cuff [23]. Prior to engaging the stapler, the amount of bladder cuff being stapled should be noted and it should be ensured that the contralateral ureter and ureteral orifice are safely away from the intended staple line.

Robot-assisted laparoscopic distal ureterectomy

The robot-assisted approach to the distal ureterectomy and bladder-cuff excision has the advantage of being able to emulate the open technique. Initial experiences have described performing the nephrectomy and proximal ureteral mobilization using a traditional laparoscopic approach, then docking the robot for the distal ureterectomy [30]. Rha *et al.* have described a technique using 8-mm robotic ports placed through 12-mm ports to perform the entire procedure robotically with the patient in the lateral flank position and without redocking the robot. Once pneumoperitoneum is established, a 12-mm port is placed periumbilically. An 8-mm robotic port is placed along the lateral rectus border 4 cm inferior to the umbilicus, while the 12-mm port is placed in the midline between the xiphoid process and the umbilicus. The second robotic 8-mm port is then "telescoped" into the 12-mm port in the midline below the xiphoid process. Finally, a 12-mm assistant port is placed between the umbilicus and the pubic symphysis. Once the nephrectomy and proximal ureteral dissection is carried as far distally as possible, the robot arms are moved to different ports. The first arm is moved from the "telescoped" port to the port lateral to the rectus muscle. The robotic port is removed from the midline subxiphoid 12-mm port and then placed through the initial 12-mm assistant port originally placed between the pubic symphysis and the umbilicus. The camera is kept in the periumbilical port. From this configuration, the distal ureterectomy and bladder-cuff excision are performed. The cystotomy is sutured closed in two layers and the specimen is removed *en bloc* through an extended umbilical incision [31].

Results

Laparoscopic and hand-assisted radical nephrectomy

Since the original description of the laparoscopic nephrectomy in 1991, the minimally invasive approach to radical nephrectomy has gained wide acceptance throughout the urologic community and is now considered the treatment of choice for isolated renal masses not amenable to nephron-sparing surgery [32]. As urologic surgeons adopted the LRN, multiple series have been published touting its comparable oncologic outcomes to those for open radical nephrectomy (Table 83.1). The longest current series runs over 11 years postoperatively. The overall, cancer-specific, and recurrence-free survival rates at 10 years in this group were 65%, 92%, and 86%, respectively. From this series, 71% of renal masses were T1, 15% were T2, and 10% were T3a [32]. Several series have also demonstrated equivalent oncologic outcomes when comparing HALN to the open approach. Though these studies were limited by their retrospective nature, their results are nonetheless compelling [33–35]. Finally, with minimally invasive approaches to radical nephrectomy, patients benefit from less pain and shorter hospital admissions [33, 36]. Although RLRN should have similar outcomes to LRN, the data are not mature.

Table 83.1 Outcomes of hand-assisted laparoscopic (HALN), pure laparoscopic, and open radical nephrectomies.

Study	Patient number	Approach	Mean or median follow-up	Recurrence-free survival (%)	Cancer-specific survival (%)
Chung *et al.* [33]	54	HALN	47 months	91	94

Laparoscopic and hand-assisted radical nephroureterectomy

The benefits of minimally-invasive approaches to upper tract urothelial cell carcinoma are similar to those seen with similar techniques used for renal masses with respect to patient discomfort and duration of hospitalization. The immediate concern with evaluating the efficacy of the nephroureterectomy lies ultimately in its oncologic outcomes. Several studies have detailed either long follow-up periods for cohorts of laparoscopic nephroureterectomies (LNUs) or have compared the laparoscopic to the traditional open approach.

Muntener *et al.* published their series of LNUs where 39 patients were followed postoperatively for a median of 74 months. Twenty-seven (69%) had a recurrence during the follow-up period. This group also had nine (23%) nonurothelial recurrences, while 11 patients died from their disease [37]. It was concluded that these results were similar to those reported with the open approach. Berger *et al.* also reported a total of 100 LNUs performed between 1997 and 2005 with a median follow-up of 7 years. The 7-year overall, cancer-specific, and recurrence-free survival rates were 50%, 72%, and 36%, respectively. Importantly, the nonurothelial 7-year recurrence-free rate for this group was 82% [38]. Both series, which document long-term follow-up, demonstrate comparable results to open nephroureterectomy.

In 2009, Simone *et al*. published their results from a prospective, randomized trial comparing laparoscopic to open nephroureterectomy. Forty patients were randomized to each group and followed for a mean of 41 months. Overall cancer-specific and recurrence-free survival were similar between the two groups. However, for T3 disease and high-grade tumors, the laparoscopic group had a poorer cancer-specific survival [39]. This is in contrast to an earlier study by Waldert *et al*. who documented similar survival rates between the laparoscopic and open approach on multivariate analysis, regardless of tumor grade or stage [40]. Clearly, further work is needed with respect to high-grade and stage tumors, though preliminary evidence appears promising.

Multiple approaches exist for managing the distal ureter for upper tract urothelial cell carcinoma (Table 83.2). In 36 patients, Matin *et al*. compared laparoscopically stapling the distal ureter after cystoscopically incising and fulgurating the intramural ureter to using needlescopic ports to excise the intramural ureter. They found that stapling was associated with higher positive margin rates as well as lower overall and recurrence-free survival. However, it should be noted that those who underwent laparoscopic stapling had confounding factors preventing the placement of needlescopic ports [29]. Brown *et al*. retrospectively compared four different techniques for distal ureteral management in their series of hand-assisted LNUs: cystoscopic disarticulation with a Collins knife; distal ureteral laparoscopic stapling; open distal ureterectomy; and *en bloc* hand-assisted distal ureterectomy with bladder-cuff excision. No cases of either a positive surgical margin or extravesical pelvic recurrence were noted in the 16 patients who underwent cystoscopic disarticulation, or in the three patients who received the open approach to the distal ureter. Two of the seven patients who received distal ureteral stapling were found to have positive surgical margins, though no pelvic recurrences were found. Finally, in the 29 patients who underwent hand-assisted *en bloc* distal ureterectomy, three positive margins and one pelvic recurrence were noted [41]. Both these studies illustrate the variety of ways in which to approach the distal

Table 83.2 Local recurrence and distant metastatic rates for different distal ureter management strategies.

Study	Distal ureter management	Patient number	Mean or median follow-up	Nonurothelial local recurrences (%)	Distant metastases (%)
Matin and Gill [29]	Lap stapling	12	23 months	8.3	25
Brown *et al.* [41]	Lap stapling	7	24 months	0	0
Hattori *et al.* [53]	Lap stapling	53	17 months	11	4

ureter, yet no clear conclusions can be made at this point.

Though the benefits of lymphadenectomy during radical cystectomy have been established, performing a lymph node dissection for upper tract urothelial cell carcinoma remains controversial. Lughezzani *et al*. reviewed data from a cancer registry and compared cancer-specific survival rates in those who underwent lymphadenectomy to those who did not. Specifically, they found no difference in cancer-specific survival between those who were pNx and pNo on multivariate analysis. One shortcoming of this study, however, is the nonstandardization of the patient population; the extent of lymph node dissection performed at each center was not documented [42]. This is in contrast to the study by Kondo *et al*. in a cohort of patients who underwent nephroureterectomies and in whom it was documented whether they received either complete or incomplete regional lymphadenectomies [43]. Regional lymph nodes were defined based on tumor location. Complete and incomplete lymph node dissections demonstrated a nonsignificant increase in cancer-specific survival within the entire group. However, when those patients with pT3–4 disease were subcategorized, both complete and incomplete lymph node dissections demonstrated a statistically significant improvement in cancer-specific survival. Finally, on multivariate analysis, complete lymph node dissection was a significant prognostic factor in those with pT3–4 disease, whereas incomplete lymph node dissection was not, suggesting that the extent of nodal dissection is important. These data are supported by a more recent multi-institutional study comparing pNx to pNo patients who underwent radical nephroureterectomy [44]. Although no cancer-specific survival benefit was conferred in those with a pT1 primary tumor, patients with pT2–4 primary tumors who underwent a lymphadenectomy were found to have significant improvement in cancer-specific survival.

Finally, the question remains of whether a lymphadenectomy may be adequately performed using minimally invasive techniques. Data comparing an open lymphadenectomy cohort for upper tract urothelial carcinoma to those who underwent laparoscopic lymphadenectomy demonstrated no difference in nodal yield or density [45]. Whether this will also be the finding with the robotic approach has yet to be determined. With growing support for performing routine lymphadenectomies in conjunction with radical nephroureterectomy, additional studies are needed to demonstrate oncologic equivalence of minimally invasive approaches to this surgical technique.

Conclusions

Significant advances have been made in the field of minimally invasive surgery and these have yielded impressive gains in patient convalescence, while providing sound, oncologic management for renal and urothelial malignancies. New advances in nephron-sparing surgery have further improved patient outcomes, while still providing the benefits conferred by laparoscopy. With the development of robotic technology, these advances can be utilized by those with less advanced laparoscopic skills, thus extending the reach of minimally invasive surgery to a greater number of patients.

CHAPTER 84

Renal Surgery for Malignant Disease: Nephron-Sparing Surgery

Pascal Zehnder, Manuel S. Eisenberg & Inderbir S. Gill
USC Institute of Urology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Introduction

Historically, open partial nephrectomy (OPN) was introduced for patients with imperative indications for nephron-sparing surgery like solitary kidney, renal dysfunction, or bilateral tumors. When laparoscopy initially emerged in 1991 for oncologic kidney surgery, malignant conditions were exclusively treated with radical nephrectomy. In 1993, Winfield was the first to describe laparoscopic partial nephrectomy (LPN) for benign disease [1]. Since then, LPN has undergone a continuous evolution and today the majority of clinical T1a (<4 cm) and many clinical T1b (4–7 cm) kidney tumors in high-volume centers are being treated with elective LPN [2]. Guidelines released by both the American Urological Association (AUA) and the European Association of Urology (EAU) recommend LPN as a standard of care for renal masses up to 7 cm [3, 4]. In experienced hands, the indications may even be expanded to patients at higher surgical risk and those who have anatomically more demanding tumors.

As the surgical steps have been mastered and the oncologic outcomes demonstrated to be comparable to those of OPN [5], the optimization of postoperative kidney function has increasingly become a focus of interest. Chronic kidney disease is a substantial concern in the general elderly population with comorbid conditions. Therefore, subjects undergoing kidney surgery for T1 tumors should, if oncologically acceptable, have as much parenchyma as possible preserved, irrespective of age [6]. While nephron-sparing surgery itself decreases long-term morbidity when compared to radical nephrectomy [7, 8], recent data have demonstrated that the length of perioperative ischemia is proportionally responsible for increased risk of acute postoperative renal failure and new-onset stage IV chronic kidney disease [2].

The minimally invasive laparoscopic and robotic approach allows for decreased postoperative pain, faster convalescence, and shorter length of hospital stay when compared to the open procedure. However, LPN and robot-assisted partial nephrectomy (RAPN), with their increased technical demands, require extensive experience and specialized skills.

Laparoscopic partial nephrectomy

Absolute indications

Bilateral kidney tumors and tumors in a functionally or anatomically solitary kidney represent an absolute indication for partial nephrectomy. While solitary kidneys are a challenge during the peri- and post-operative course, with special focus on fluid and electrolyte balance, controlled surgical and oncologic outcomes have been documented in several studies [9].

Relative indications

Conditions such as pre-existing renal dysfunction, metabolic syndrome, nephrotoxic drug intake (e.g. future need for chemotherapy), genetic predisposition to meta-

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

chronous renal cell carcinoma (e.g. von Hippel–Lindau disease), renovascular disease, recurrent kidney stones, etc. create the risk for future kidney functional impairment. These clinical conditions constitute a relative indication for nephron-sparing surgery.

Elective indications

The widespread use of routine body imaging led to a significant increase in incidentally-diagnosed small renal masses (<4 cm). The term elective partial nephrectomy describes the resection of a localized unilateral kidney tumor with a healthy contralateral organ, and today represents the most common indication for nephron-sparing surgery.

Clinical scenarios

Clinical T1a tumors (<4 cm)

Initially, LPN was restricted to patients with tumors of 4 cm or smaller in size. The reality is that nephron-sparing surgery in this cohort is still underused, as many cT1a lesions are treated with laparoscopic radical nephrectomy in the community [10, 11]. This is due to the fact that LPN is a technically-demanding surgery, mainly due to the requirement for intracorporeal suturing under ischemia-related time pressure. However, availability of the requisite technical expertise, especially at centers of excellence, has made LPN a preferred treatment modality for many elective cases with cT1a tumors in the presence of a normal contralateral kidney. OPN and laparoscopic radical nephrectomy are now typically reserved for more complex cases and special clinical scenarios.

Clinical T1b tumors (4–7 cm)

Mature series describe 9–23% of tumors of 4–7 cm in size being treated with LPN [12, 13]. In a tertiary center, up to 60% of patients with cT1b tumors underwent elective partial nephrectomy [14]. Interestingly, the risk of dying from clinical T1b kidney cancer is similar, irrespective of whether patients undergo partial or radical nephrectomy. Leibovich *et al*. documented 5-year recurrence-free survival rates following partial and radical nephrectomy for cT1b tumors at 94% and 98%, respectively [15]. These larger tumors are typically more complex as they are more likely to be in proximity to functionally important structures, such as hilar vessels and the collecting system. However, several series have demonstrated similar outcomes when comparing LPN for cT1a and cT1b tumors, including similar operative efficacy (estimated blood loss, operative time, intraoperative complications, conversion rates), perioperative outcomes, and pathologic success rates (positive surgical margins, recurrences, etc.). Equivalent outcomes have also been documented when comparing LPN with OPN for T1a lesions [11, 15, 16]. These reassuring results, together with the technical improvements, are the rationale for the minimally invasive nephron-sparing approach for larger kidney tumors.

Expanding indications

Common techniques for partial nephrectomy, open or laparoscopic, employ warm ischemia by means of hilar vessel clamping. Once the renal hilum is clamped, every minute may count. Ischemia time is a limiting factor when it comes to more complex lesions. Finally, tumor size, tumor location, patient comorbidities, and the surgeon's experience determine whether surgery is performed with a minimally invasive or open approach.

Hilar tumors

Optimal preoperative planning involves thin-slice (1 mm) computed tomography (CT) imaging with three-dimensional (3D) reconstruction. Unlike tumors in other locations, careful hilar dissection is necessary to delineate which vessels directly supply the tumor, and therefore can be ligated, without causing collateral ischemic damage to normal healthy parenchyma. Intraoperative laparoscopic ultrasound is employed to delineate the tumor size, contour, proximity to collecting system, and circumferential scoring to achieve negative surgical margins. Finally, tumor dissection takes place in a lateral to medial direction, following the vessels in a parallel fashion. This is preceded by early control of any tumor-entering vessels, while preserving vital blood supply to the remaining parenchyma. Precise reconstruction with superficial stitches is mandatory as deep parenchymal suturing carries the risk of occluding the remaining vessels. Although perioperative data (estimated blood loss, operative time, and positive margin rate) as well as oncologic outcome are comparable with contemporary series, the close relation to relevant vascular structures and the pelvicalyceal system is reflected by the considerable number of postsurgical complications. The majority of cases (75–88%) require the repair of the collecting system, and in more than 20% of cases the postoperative course of hilar tumors is complicated by problems such as postoperative hemorrhage and urinary leakage, even in a center of excellence [17, 18].

Central tumors

Central tumors commonly invade the collecting system or the central renal sinus fat on staging imagery, and

represent approximately 55–63% of cases in current series. While the central tumors were larger than the peripheral tumors in a series comparing 154 central with 209 peripheral kidney tumors, the estimated blood loss as well as overall complication rates were similar for the two groups. However, the central tumors were associated with a longer operative time, longer length of stay, more early postoperative complications (6% vs 2%, $P = .05$), and most importantly, longer warm ischemia time (34 min vs 30 min, $P < .001$) [19]. Another series confirmed the difference in tumor size (LPN: central tumors 3.2 cm vs peripheral tumors 2.5 cm, $P < .05$) but was unable to show any difference for the perioperative features [20]. Again, the surgeon's experience is of upmost importance.

Completely intraparenchymal tumors

Intraoperatively, this subset of lesions is exclusively detected by renal ultrasonography as the tumor reveals no exophytic component. They are completely covered by normal appearing parenchyma and are often in close proximity to central structures. With the aid of ultrasonography, the resection boundaries are marked on the kidney's fibrotic capsule. In nearly all cases, the resection opens the collecting system [21], resulting in a cuneiform tissue defect. This is one of the few occasions a preprepared hemostatic Surgicel bolster helps to fill the parenchymal tissue gap, as described later.

Obesity

The crucial issues in the obese patients are proper positioning and trocar placement. The best possible padding is extremely important because these patients are at increased risk of rhabdomyolysis. The large body volume increases distances. Therefore, trocars have to be shifted laterally and the use of bariatric instruments is required to assure sufficient reach. Studies comparing LPN with OPN in obese patients report that LPN affords a shorter operative time (186 min vs 266 min), decreased warm ischemia time (26 min vs 44 min), lower estimated blood loss (300 mL vs 450 mL), and fewer intra- and post-operative complications (20% vs 50%) ($P < .05$ for all) [22].

Solitary kidney

Partial nephrectomy for a tumor in a solitary kidney is challenging irrespective of the type of approach. The lack of functional reserve due to the absent contralateral kidney, with potentially detrimental outcome in case of perioperative problems, clearly indicates the need for referral of such patients to experienced centers. Only established teams, including surgeons, anesthesiologists, and potentially intensive care providers, can assure successful outcome. In an early series, LPN revealed, even in patients with smaller tumors, a longer warm ischemia time (29 min vs 21 min, $P = .003$), more intraoperative complications (17% vs 1%, $P < .001$), and more postoperative complications (43% vs 24%, $P = .02$) when compared to OPN [9]. The duration of warm ischemia time and complication rate remain critical issues in other series as well [23, 24]. However, newer approaches, like the established early unclamping technique [25] or the development of clampless techniques, are promising in experienced hands. However, the threshold for intraoperative conversion to open surgery should definitively be lower in patients with a solitary kidney.

Multiple ipsilateral tumors

In view of the potential for contralateral recurrence, nephron-sparing surgery is the preferred treatment for patients with multiple, small ipsilateral tumors. The limiting factor, besides volume of remaining healthy parenchyma, is the warm ischemia time [26]. A detailed imaging study provides the necessary information to establish an efficient resection strategy. The procedure starts with the clampless resection of the simplest lesion. Hilar clamping is reserved for the resection of more complex masses. Ideally, only one or two resections have to be performed under warm ischemia, followed by a reasonable extent of reconstruction. Alternatively, all tumors are resected *en bloc*. This requires their presence in closest relation in order to avoid the sacrifice of significant amounts of healthy parenchyma. Based on the limited oncologic outcome data available, LPN combined with cryotherapy represents another option for a select group of patients [27].

Previous ipsilateral kidney surgery

In their feasibility analysis, Turna *et al*. emphasized that for all of their 25 cases, a meticulous adhesiolysis was paramount to successful completion [28]. Especially with a retroperitoneal approach, extensive digital dissection prior to balloon dilatation was necessary. In order to avoid major vascular complications, detailed hilar dissection within potentially dense adhesions was omitted. Subsequently, hilar occlusion was performed with the use of a Satinsky clamp instead of bulldog clamps.

Multiple renal arteries

In the presence of multiple hilar arteries, hilar Satinsky cross-clamping controls the major blood supply, while distant polar arteries should be individually dissected,

allowing for selective bulldog clamping [29]. This setting underlines the need for optimal preoperative imaging studies. However, the surgeon must remain vigilant for potentially undetected vessels.

Cystic tumors

LNP for radiologically suspicious cystic tumor requires considerable caution. The procedure is technically more challenging due to the substantial risk for inadvertent cyst rupture and cellular spillage. Spaliviero *et al*. compared 50 patients with cystic kidney lesions to 50 consecutive patients with a solid renal mass. Both cohorts underwent uneventful LPN with similar perioperative outcomes, in particular no positive surgical margins or cystic rupture. However, one patient with an initial cystic lesion had a recurrence in the retroperitoneum at 1 year [30].

Surgical technique

Access

The surgical access to the kidneys can be achieved retro- or trans-peritoneally. Historically, the lumbotomy takes the extraperitoneal approach. Retrospective outcome studies investigating both of the minimally invasive accesses available demonstrate that the retroperitoneoscopic approach offers decreased operative time, lower estimated blood loss, faster time to resumption of a regular diet, and shorter length of stay, with similar warm ischemia time [31]. In addition, the retroperitoneoscopic approach offers the advantage of isolating any hemorrhage or urine leakage from the peritoneal cavity. This may be a benefit for particular medical conditions, like advanced liver cirrhosis [32]. However, a prospective randomized comparison of 102 patients revealed only a quicker hilar control and shorter operative time with retroperitoneoscopy, while all other patient outcomes were similar for both approaches [33]. We favor the transperitoneal approach because it offers more familiar landmarks, a larger working space with consecutively greater versatility of instrument angles, and most importantly, technical ease of intracorporeal suturing. The full renal mobilization allows the kidney to be rotated as required to provide optimal exposure of any mass regardless of its location. In addition, it offers enough space to place the Satinsky clamp and therefore avoids the time-consuming placement and removal of individual bulldog clamps. However, the retroperitoneoscopic route is an option in patients with expected severe adhesions due to multiple previous abdominal surgeries or in morbidly obese patients. The minimally invasive urologist should be familiar with both approaches and the final choice should be based on patient anatomy, the procedure to be performed, and the surgeon's preference [34].

Port placement for the laparoscopic approach

Depending on surgeon preference, three to five trocars can be employed routinely for LPN. While the three-port method requires the use of bulldog clamps, five trocars allow the introduction of a retractor and a Satinsky clamp. From our experience, we prefer the use of five trocars because this offers the safest and most efficient access (Figures 84.1 and 84.2).

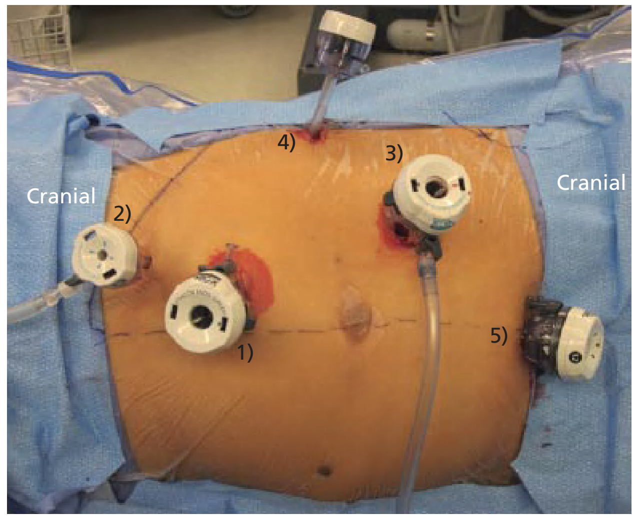

Figure 84.1 Left laparoscopic port placement (upper pole lesion). 1, 12-mm camera port; 2, 5-mm left-hand working instrument; 3, 12-mm right-hand working instrument; 4, 5-mm assistant port; 5, 12-mm port for Satinsky clamp.

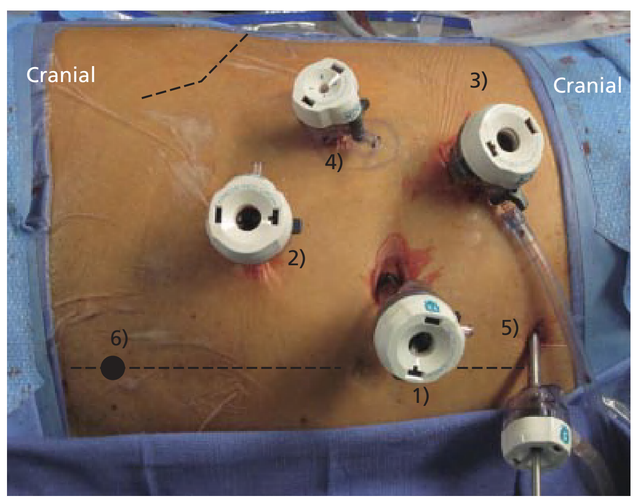

Figure 84.2 Right laparoscopic port placement (lower pole lesion). 1, 12-mm camera port; 2, 12-mm left-hand working instrument; 3, 12-mm right-hand working instrument; 4, 5-mm assistant port; 5, 5-mm port for liver retractor; 6, position of Satinsky clamp.

Surgery step-by-step

The colon is widely mobilized from Gerota's fascia so that it falls off the kidney medially without the need for constant retraction. Caudal to the lower pole of the kidney, the ureter and gonadal packet are lifted off from the psoas muscle. Dissection proceeds cephalad along these structures on the anterior surface of the psoas muscle until the renal vein is identified. The hilar vessels are carefully dissected *en bloc*. Except for the renal fat immediately over the tumor, the kidney is completely mobilized and defatted within Gerota's fascia. With a flexible 7-MHz ultrasound probe, the tumor margin is circumferentially identified and the future resection line scored with electrocautery, with consideration for an adequate margin of normal renal parenchyma around the tumor. Approximately 30 min prior to clamping, 12.5 mg of mannitol and 10 mg of furosemide (Lasix) are given. With a laparoscopic Satinsky clamp brought in through a 12-mm trocar placed in the midline suprapubic region, the renal hilum is clamped *en bloc*. The bloodless conditions allow for identification of the healthy parenchymal margin, and the tumor is then excised with cold Endoshears (Figure 84.3) and finally placed in an Endobag. During the resection, any large vessels or collecting system tributaries can be prospectively clipped with Hem-o-lok clips (Weck Closure System, Research Triangle Park, NC, USA) (Figure 84.4). Next, one to several horizontal running mattress sutures (Vicryl 2-0 on a CT-1 needle) are used to ensure hemostasis and to repair any collecting system violations (Figure 84.5). The sutures can be individually tied or a Hem-o-lok clip can be placed on each end to secure the suture and prevent it from pulling through. Retrograde injection of diluted methylene blue through a preoperatively inserted ureteral stent confirms water tightness.

After performing the horizontal mattress sutures, the parenchymal defect is covered with FloSeal (gelatin matrix thrombin sealant; Baxter Healthcare, Deerfield,

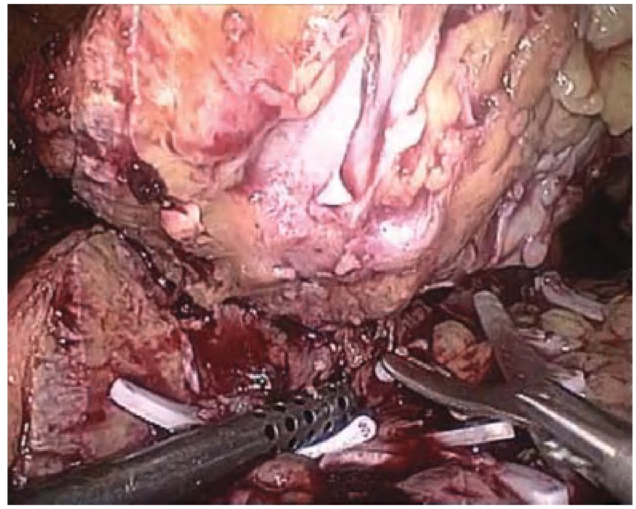

Figure 84.4 While sharply dissecting the fragile parenchyma, presenting vascular or other solid structures (collecting system) are secured with Hem-o-lok clips. With suction pressing the ancient tumor bed downwards, the dissection upwards along the posterior contour can be eased.

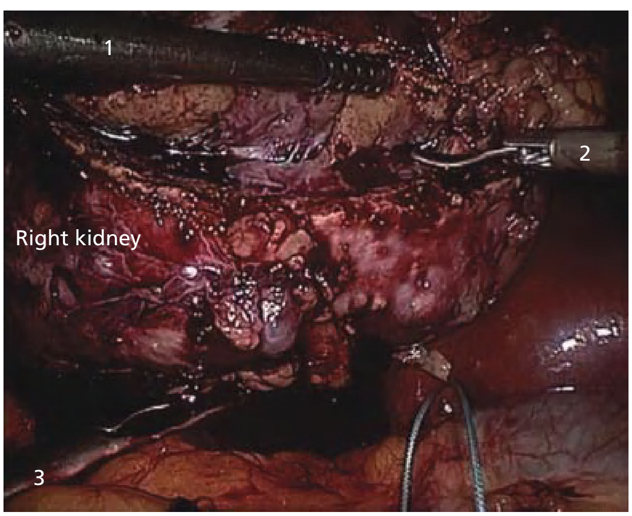

Figure 84.3 Suction in the left hand allows the tissue to be lifted up, nicely presenting the cutting edges. Tumor resection is performed with cold Endoshears in the bloodless operative field, respecting a margin of healthy parenchyma around the lesion. 1, Suction; 2, Endoshears; 3, Satinsky clamp.

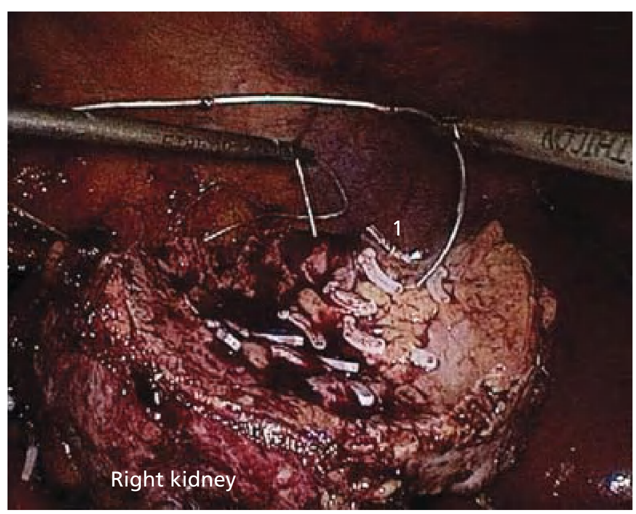

Figure 84.5 Horizontal running mattress sutures typically start outside the resection bed. The thread is anchored with a Hem-o-lok clip (1). The stitch passes horizontally just below the clips applied during the previous resection. One hand guides the needle while the other hand maintains traction on the suture.

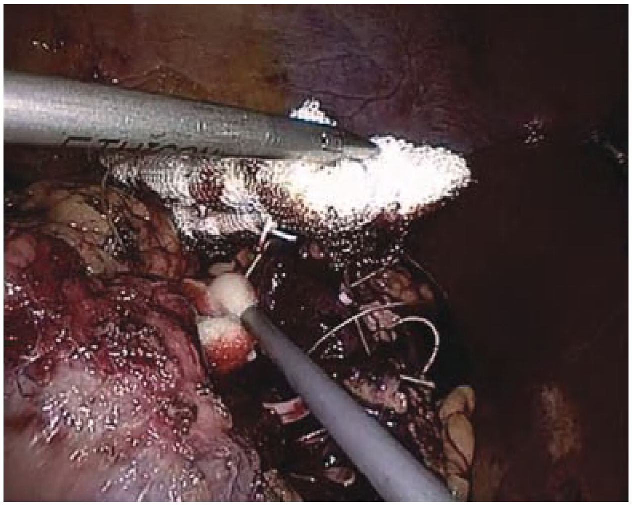

Figure 84.6 Substantial parenchymal defects are first filled with the hemostatic tissue sealant FloSeal, and finally covered with the a preprepared Surgicel bolster.

IL, USA), a biologic hemostatic tissue sealant, and an unfolded Surgicel gauze. More substantial renal parenchymal defects are first filled with the same tissue sealant and then covered with a preprepared Surgicel bolster (Johnson & Johnson, New Brunswick, NJ, USA) (Figure 84.6). If a bolster is used, several more horizontal mattress sutures are used to approximate the parenchymal borders to guarantee adequate tissue compression. Eventually, the entire resection site is covered with a layer of fibrin glue (Tisseel; Baxter Healthcare). After confirmed hemostasis, 12.5 g of mannitol and 10–20 >mg of furosemide are given, and the Satinsky clamp opened and removed. The Endobag with the specimen is retrieved and a Jackson–Pratt drain placed, mostly through the 5-mm assistant port in the flank.

Hemostasis

For this crucial step, several strategies have been advocated. However, we strongly emphasize that advanced LPN necessarily requires the performance of unconditional intracorporeal free-hand suturing. In addition, energy sources, selective use of surgical clips, adjunctive hemostatic/sealant agents [35, 36], and bolsters are individually used in addition.

Hilar control

There are two ways to clamp the blood supply prior to beginning the tumor resection. The application of laparoscopic bulldog clamps on the hilar vessels requires a meticulous vascular skeletonization. In addition, several technically challenging maneuvers are necessary to clamp and unclamp the circulation, and there is still the risk of bleeding due to unidentified accessory hilar vessels. Therefore, we favor the use of a laparoscopic Satinsky clamp, introduced with or without a 12-mm suprapubic port, cross (*en bloc*)-clamping the hilum. The accessory port is out of the surgeon's working instrument range and this allows for easy handling of the Satinsky clamp. However, both techniques, bulldog and Satinsky clamp, provide sufficient visualization for exact tumor excision, pelvicalyceal repair, and hemostatic parenchymal suturing in a bloodless field. In addition, the artery-only clamping technique has been established in order to decrease the renal damage during warm ischemia. However, renal functional improvements could not be demonstrated in an animal model and the impaired visualization with the increased risk of hemorrhage has only lead to a limited application of this approach [37, 38].

Renal ischemia

Huang *et al*. demonstrated that 26% of our surgical kidney cancer patients had a certain degree of impaired renal function at baseline. In addition, patients undergoing radical nephrectomy are more likely to develop new-onset chronic kidney disease compared to patients undergoing partial nephrectomy [39]. Because all the kidney's metabolic activities require oxygen, the renal cortex is extremely sensitive to ischemia. With the arterial blood supply clamped, energy sources providing structural and functional cellular integrity break down [40, 41]. Subsequently, failure of the cellular membrane transport mechanisms leads to cellular death. While select small, peripheral, exophytic kidney tumors are resectable with an unclamped technique, deep parenchyma invading lesions are most commonly performed using some form of hilar occlusion. The safe duration of ischemia remains controversial. Experimental studies describe the beginning of renal damage and cellular degeneration of the nephron after 20–30 min of clamping. Ischemia itself acts on the physiologic part of the parenchyma and is not the only prognostic factor impairing the renal function. The pure extent of remaining healthy kidney parenchyma depends directly on the tumor size as this defines the resection widths. In addition, extensive reconstructive and hemostatic suturing has a deleterious effect on the remaining healthy parenchyma. Thompson *et al*., recently showed in a large series (n = 458) of patients with solitary kidneys, that those managed with warm ischemia are significantly more likely to develop acute renal failure in the postoperative period as well as new-onset stage IV chronic kidney disease during follow-up compared to those managed without hilar clamping [42]. This study indicated that an upper limit of 25 min warm ischemia time should not be exceeded. It is crucial to know that every 5 min of warm ischemia time is associated with a

$2.2\,mL/min/1.73\,m^2$ decline in glomerular filtration rate [9]. According to an expert panel, warm ischemia time is the strongest modifiable surgical risk factor for postoperative kidney disease and should therefore be kept to less than 20 min [38]. For patients with complex tumors most probably requiring ischemic times longer than 20–30 min, strong consideration should be given to hypothermic conditions, allowing for longer clamping. Laparoscopically, the kidney can be cooled with ice slush on the organ's surface, instillation of cold saline through a retrograde ureteral catheter, and/or intra-arterial perfusion of cold saline/lactated Ringer's [43–45].

While for OPN, cold ischemia is the method of choice, warm ischemia via hilar cross-clamping is the method widely used in the minimally invasive setting. This technique has developed to allow early unclamping, with a dramatic improvement regarding warm ischemia time [25]. This development was necessary because larger series have documented critically long warm ischemia times in the 23–35 min range [12, 13, 37, 46]. With the early unclamping technique, cold resection is performed under warm ischemia time. Major vessels and collecting system parts are successively closed with Hem-o-lok clips. After the tumor resection, a single hemostatic horizontal running mattress suture is performed within the resection bed, below the previously applied clips. Thereafter, the Satinsky clamp is opened briefly to reperfuse the kidney and evaluate hemostasis. If the bleeding is found to be acceptable, the Satinsky clamp is removed. Individual areas of hemorrhage are controlled with additional suturing, allowing for adequate visualization to guarantee optimal further vessel ligation, collecting system repair, and renorrhaphy with/without a bolster. In our series, this technique halved warm ischemia time from a median of 31.9 min to 14.4 min [12]. Although estimated blood loss increased, the rate of postoperative hemorrhage decreased. This is likely due to identification of transected vessels in the reperfused resection bed. Further attempts focusing on zero ischemia time have been successfully developed in our institution and have been demonstrated at several live surgery symposiums. However, this latest technology requires further refinement before it can be implemented in general practice.

Manual/instrumental compression of renal parenchyma is a great option in open or hand-assisted surgery, mainly for polar lesions. In select cases (e.g. polar lesions), it even allows complete omission of hilar clamping. However, the hilar vessels should always be accessible for emergent clamping. Excessive compression potentially leads to tissue trauma; therefore, bowel clamps, tourniquets or other instruments applicable in the minimally invasive setting have to be used carefully. Due to the reduction in time sensitivity, parenchymal compression potentially allows a larger cohort of surgeons to perform LPN.

There is ongoing contention regarding the impact of intermittent kidney perfusion by sequential clamping and unclamping in the course of a partial nephrectomy. The data from animal studies are conflicting [47, 48]. Additionally, ischemic preconditioning, extensively studied for liver surgery, has never been analyzed for human kidneys [49, 50]. Therefore no evidence-based general statement can be made about what the best action is if there is substantial, uncontrolled hemorrhage from the resection bed after unclamping. In our experience, we prefer a limited reclamping to achieve the necessary visualization for precise hemostasis. The conversion to open surgery is definitively a valuable option. However, the time requirement to perform the access has to be taken into the time considerations.

Contemporary outcomes

In short, LPN evolved from a burgeoning procedure to the standard of care for the majority of renal masses, recommended by the established American and European guidelines of urology [3, 4]. Despite increasing tumor complexity, warm ischemia time, complication rate, postinterventional kidney function, and oncologic outcomes have significantly improved and are today comparable to OPN. The fact that radical nephrectomy for the treatment of small renal masses is still widely performed reflects the required surgical skills for LPN [10]. However, at tertiary centers of expertise, LPN will likely replace OPN in the near future as the reference standard treatment for the majority of patients with a surgical renal mass.

Comparison between open and laparoscopic partial nephrectomy

Compared to OPN, the earlier gold standard of care, LPN was initially performed on smaller and more peripherally located tumors. This partially explains its lower blood loss and shorter operative time. Of course, the minimally invasive approach offers shorter hospital stay followed by faster convalescence. However, patients undergoing LPN revealed more postoperative complications, conversions to radical nephrectomy, longer warm ischemia time, and a higher postoperative hemorrhage and reintervention rate. This is confirmed by the findings of a recent meta-analysis of the AUA [4]. On the other hand, intraoperative complications, positive surgical margin rates, oncologic and functional 3-year data were similar, as shown in the comparison of LPN and OPN performed in 1800 patients with a single renal tumor (<7 cm) at major centers with greatest expertise [51].

With increasing experience and technical development, LPN outcomes have significantly improved. In their consecutive single-surgeon series, Gill *et al*. showed that despite the targeted tumors progressively increasing in complexity over time, warm ischemia time, and overall postoperative and urologic complications decreased remarkably [12].

Tables 84.1 and 84.2 summarize perioperative data and complication rates of four LPN versus OPN comparison series.

Positive surgical margins

The central tenet of any oncologic renal surgery is the complete resection of tumor along with a margin of healthy parenchyma. In their large cohort of OPN, Yossepowitch *et al*. found 5.7% patients (77 of 1344 patients) to have positive surgical margins on final pathology. All were treated expectantly. The recurrence-free survival at 10 years was 93% both for patients with positive and negative surgical margins. The investigators concluded that positive surgical margins in partial nephrectomy specimens do not uniformly indicate an adverse prognosis and therefore, select patients with a positive surgical margin can be offered vigilant monitoring without compromising long-term disease-free survival [52]. In comparison, larger LPN series, each including more than 400 patients, report positive surgical margin rates between 0.8% and 2.4% [12, 35, 51, 53, 54]. However, we strongly advocate several intraoperative frozen sections from the tumor bed. Besides the medicolegal aspect, this eventually helps to estimate the recurrence risk in case of unexpected positive surgical margins on the final pathology report.

Survival data

Care must be taken when comparing long-term survival data from different series because of the heterogeneous cohorts. Lane *et al*. reported a series with a minimum of 7 years of follow-up (77 LPN, 310 OPN). For pT1a tumors, the reported 7-year recurrence-free survival after LPN and OPN was 93% and 95%, respectively ($P = .7$), and disease-specific survival was 95% and 95%,

respectively ($P = 1.0$). For pT1b tumors, the 7-year recurrence-free survival after LPN and OPN was 82% and 95% ($P = .17$), and disease-specific survival was 82% and 96%, respectively ($P = .12$). In the multivariable setting, increasing age, comorbidities, hypertension, 5-year treatment failure probability based on the Kattan nomogram [55], and preoperative renal impairment, but not surgery type (LPN vs OPN) and tumor size, were significant predictors of mortality. Multiple studies with shorter follow-up support these findings [5, 13, 15, 46, 51, 56].

Robot-assisted partial nephrectomy

Being well established for the treatment of prostate cancer in the small pelvis, RAPN has become a rapidly emerging approach for the treatment of kidney cancer [57–61]. The wrist function of the robotic arms provides an advantageous angle to perform the crucial resection in the depths of the renal parenchymal bed and facilitates the intracorporeal suturing.

However, there are some technical considerations. Once the robot is docked, table rotation becomes impossible. Therefore, depending upon tumor location and consecutive trocar placement, the initial part of the intervention may be performed using standard laparoscopy with the use of the robot only for tumor resection and renal reconstruction. The majority of authors prefer a flank position with the table moderately flexed [62–64]. Because the robot-assisted procedure requires additional trocars compared to standard LPN, this allows for better spacing of instruments and fewer clashing incidents of the robotic arms. The exchange of robotic instruments and technical robotic failures in the course of warm ischemia remain critical issues. The port-in-port technique of RAPN, wherein the 8-mm robotic ports are inserted through two standard 12-mm laparoscopic ports, represents a valuable option in the initial learning curve to avoid wasting precious time in case of an emergent conversion to conventional LPN. No new port placement is required because CT-1 or CT-X needles may be directly introduced through the 12-mm ports in place once the robot is undocked [64].

Port placement for the robot-assisted approach

As mentioned, the entire procedure may be performed with the aid of the robot or the operation may be started using standard laparoscopy with utilization of the robotic assistance only for tumor excision and renorrhaphy. However, the timing of docking the robot must be considered because with the robot docked, table rotation becomes impossible.

For institutions with a three-arm robot configuration, four to five trocars are necessary: a 12-mm periumbilical camera port, a 8-mm subcostal robotic trocar in the anterior axillary line, a 8-mm robotic trocar in the posterior axillary line one cross finger above the iliac crest, and one 12-mm assistant trocar in the low midline to allow for passage of sutures, bulldog clamps, suction, or retraction. If deemed necessary, an additional 12-mm subxiphoid trocar may be inserted for retraction or passage of bulldog clamps from a different angle. Using a four-arm configuration involves five to six trocars. The same trocar configuration can be used as demonstrated for the standard laparoscopic approach (see Figures 84.1 and 84.2), but the robotic trocars should be shifted slightly to avoid clashing of the three arms. The table-side assistant is responsible for clamping the renal hilum, providing suction and retraction, delivering and cutting sutures, and clip placement.

In available preliminary retrospective studies, RAPN has demonstrated equal [64] or even improved [65] perioperative outcome compared to LPN. However, feasibility is by far not the most important endpoint. In addition, the robot-assisted approach is associated with increased costs and cosmetic inferiority due to the need for additional port placement. Therefore, to determine the true value of RAPN for treatment of renal cell carcinoma, prospective randomized studies with longer follow-up are mandatory.

CHAPTER 85

Laparoscopic and Robotic Adrenalectomy

Daniel Yong,[1] Matvey Tsivian[1] & David M. Albala[1,2]

[1]Division of Urology, Department of Surgery, Duke University Medical Center, Durham, NC, USA

[2]Associated Medical Professionals of NY, Syracuse, NY, USA

Introduction

Since it was described in 1992 [1], laparoscopic adrenalectomy (LA) has become the standard of care for a variety of adrenal lesions in many centers around the world. Multiple studies have reported significant advantages with the laparoscopic approach when compared with the traditional open approach. This minimally invasive approach offers patients less postoperative pain, a shorter hospital stay, a faster return to normal activities, and a better cosmetic result.

In the past decade, robotic technology has been introduced to assist laparoscopic procedures. With a three-dimensional (3D) display to enhance depth perception and instruments containing a "wrist" joint to improve dexterity, robot assistance may offer advantages over standard laparoscopy, potentially reducing the technical complexity of the procedure and enabling less experienced surgeons to deliver minimally invasive surgery to their patients.

In this chapter, the current techniques and results of LA and robot-assisted LA will be reviewed in detail. Recent developments, such as laparoendoscopic single site (LESS), partial adrenalectomy, and ablative techniques, are also discussed.

Indications

LA is a safe and effective method for removal of most adrenal lesions. Current indications for LA include functioning adrenal lesions, such as aldosteronoma, pheochromocytoma, and androgen/estrogen, glucocorticoid-producing adenomas. Occasionally, symptomatic adrenal cysts and myelolipomas may be removed laparoscopically. Bilateral LA may also be performed in patients with bilateral adrenal hyperplasia (Cushing syndrome or disease). Nonfunctioning adrenal lesions larger than 4–5 cm or tumors that have shown growth in size on serial imaging may also be excised laparoscopically.

The use of laparoscopy in the management of larger malignant masses is somewhat controversial. The lack of a true capsule around the adrenal gland greatly increases the risk of local invasion of these highly aggressive tumors. This makes complete excision and adherence to basic oncologic principles a difficult task, even during open surgical approaches. It is not surprising that long-term survival rates for any surgical approach have been poor, especially when coupled with the lack of effective chemotherapeutic agents.

In light of these difficulties, many surgeons advocate an open approach to known adrenal malignancies or for large lesions (>8 cm). In spite of these fears, there have been multiple reports of effective and complete laparoscopic surgical excision of malignant masses [2, 3]. Prospective, randomized controlled trials are lacking, however, and may be slow in coming because of the relative rarity of these tumors (0.3% of all cancers). LA for adrenal metastases has also been reported to have excellent outcomes in select patients [4, 5].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Contraindications

General contraindications to a laparoscopic approach include those patients with an uncorrected coagulopathy, peritonitis, intestinal obstruction, and severe cardiopulmonary disease. The list of contraindications for LA continues to shrink as experience with laparoscopic surgery matures. Locally advanced tumors with obvious extension to surrounding structures or those with venous involvement are not candidates for laparoscopic excision and should be resected with an open approach.

Adrenal cortical carcinoma (ACC) was previously considered to be a contraindication for LA because of the concern for tumor clearance and intraoperative spillage, but recent publications suggest that laparoscopic and open approaches for noninvasive ACC have comparable outcomes when the principles of oncologic surgery are respected [2–4, 6, 7]. Although the maximal size of an adrenal lesion suitable for LA is still debated, most surgeons agree that tumor sizes of 12–14 cm represent the upper limits of LA [3]. However, it has to be noted that the overall morbidity and mortality is independent of the size of the tumor [8]. In summary, with sufficient laparoscopic experience there appears to be no size limit to the feasibility of LA.

Malignant pheochromocytomas should also be approached cautiously. Although the resection of malignant pheochromocytomas by laparoscopic approach has been reported, there are still insufficient data on the long-term follow-up of these patients [3, 7, 9, 10].

Obesity has been suggested to be a relative contraindication to a laparoscopic approach to the adrenal gland. Indeed, early series have shown a higher rate of complication (especially minor) in patients with an elevated body mass index (BMI). While more recent investigators have noted that obesity is associated with longer operating room times and slight increases in complication rates, most authors feel that obese patients are easily managed as the surgeon gains operative experience and advances along the learning curve [11].

Finally, significant previous abdominal surgery can be a relative contraindication to transperitoneal laparoscopy if adhesions are so dense as to create an unacceptably high risk of inadvertent enterotomy. In this instance, the surgeon can opt for a retroperitoneal approach, either through a standard flank incision or through retroperitoneal laparoscopy [12].

Preoperative management

A complete step-by-step discussion of the evaluation of a patient with an adrenal lesion is beyond the scope of this chapter. Clearly, each patient requires an assessment of any lesion from a radiologic perspective as well as a full metabolic evaluation.

A complete endocrinologic assessment will entail measurement of serum electrolytes, serum hormone levels, serum catecholamines, urine studies for catecholamines and their metabolites, and urine levels of steroid hormones and their metabolites. In addition, stimulation studies, such as low- and high-dose dexamethasone suppression tests, and plasma renin activity can also be applied when appropriate.

Patients with a functioning tumor may require metabolic correction. In patients with primary hyperaldosteronism, spironolactone is given preoperatively. The serum potassium levels and blood pressure should be carefully monitored. In patients with Cushing syndrome, serum glucose level needs careful monitoring and glucocorticoid replacement may be necessary. For patients with pheochromocytoma, control of blood pressure and cardiac arrhythymias is essential. This usually entails starting alpha-adrenergic blockade 2 weeks prior to surgery, with the subsequent addition of beta-blockade in the presence of arrhythmias. Some endocrinologists advocate the use of the tyrosine hydroxylase inhibitor metyrosine as preoperative medical blockade, but this regimen can be difficult to tolerate owing to side effects.

Many surgeons advocate checking a complete blood count as well. In the absence of a history of a significant bleeding or coagulopathy disorder, most patients do not require routine coagulation studies (e.g. bleeding time, PT, PTT). Any patient who is suspected of harboring a malignant mass should be evaluated for occult metastatic lesions using a chest radiograph and measurement of liver enzymes and alkaline phosphatase.

Computed tomography (CT) and magnetic resonance imaging (MRI) provide valuable information on the size of the lesion and extension of the tumor into surrounding structures, as well as characterization of the nature of the tumor. Adrenal lesions are commonly found serendipitously on imaging studies performed for other complaints, especially on CT scans. CT imaging using thin cuts, both before and after intravenous contrast, can greatly aid in the assessment of these lesions. Small lesions without enhancement after contrast and Hounsfield measurements of 15 units or less are rarely malignant and do not require further evaluation in the absence of clinical symptoms. MRI scanning can also give useful information on certain lesions such as pheochromocytoma, which has a typical bright light bulb appearance on T2-weighted images. In certain instances, ^{131}I-metaiodobenzylguanidine scintigraphy (MIBG) may be helpful, especially in localizing small or recurrent pheochromocytoma.

Preoperative preparation

A mechanical and antibiotic bowel preparation is given to all patients. This helps decompress the intestines to

facilitate exposure during dissection and allows for conservative repair of any inadvertent bowel injury. A broad-spectrum antibiotic should be given perioperatively. The patients should be typed and cross-matched for 2 units of blood.

When performing a LA, general anesthesia with endotracheal intubation is used with controlled ventilation to ensure adequate oxygenation and to avoid hypercarbia. Nitrous oxide can lead to bowel distention and should be avoided during this procedure. In addition, a nasogastric tube and urinary catheter are inserted to decompress the stomach and bladder prior to creation of the pneumoperitoneum.

As always, close intraoperative monitoring of vital signs through the use of invasive lines is crucial. This includes arterial lines, central lines, and large-bore catheters for rapid fluid infusion. Anesthesiologists should also be prepared for rapid and drastic shifts in blood pressure (intraoperative hypertension and hypotension after removal of the adrenergic lesions) and should have vasoactive medications drawn and ready for immediate infusion.

Instrumentation

Standard laparoscopic equipment as described in previous chapters is used in all approaches to the adrenal gland. For dissection, employing curved dissecting scissors connected to electrocautery or a hook cautery is clearly a matter of personal choice and experience. Using high-frequency instruments (Harmonic scapel; Ethicon Endo-Surgery Inc, Cincinnati, OH, USA) or LigaSure (Valleylab, Boulder, CO, USA) to divide the adrenal vessels (except the main adrenal vein) and the surrounding fatty tissue can offer an advantage in those patients with excessive retroperitoneal fat. Small bleeders within this redundant fat can be bothersome and difficult to control during a search for the adrenal gland and its vasculature.

Intraoperative ultrasound is occasionally helpful when searching for a small lesion to enucleate. Current devices can be passed intra-abdominally, but require a larger trocar. These instruments can be difficult to use and clearly benefit from operator experience.

A retractor is also necessary to move the spleen or the liver away from the adrenal gland to allow for complete dissection. A fan device works well and should be safe on the surrounding organs if used appropriately. Malleable, shepherd's crook retractors are also available and are particularly helpful at raising the liver off Gerota's fascia and the hepatic flexure of the colon. We frequently employ a large, blunt grasper, which can be used to sweep tissues aside, as well as to grasp an edge of exposed peritoneum and thereby lift and retract the offending object or tissues.

At the end of the procedure, a specimen entrapment bag is used to retrieve the adrenal tissue. The EndoCatch device (US Surgical Corp, Norwalk, CT, USA) is easy to open and has a nice, fixed open mouth into which the specimen is delivered. The LapSac (Cook Urological, Spencer, IN, USA), however, has been proven to be impervious and is the bag of choice for any lesion that is possibly malignant. This device can be cumbersome and requires skill to keep the mouth of the bag open while passing the specimen into its interior. In all cases, open surgical instruments should be available in the operating room in the event a conversion to an open procedure is necessary.

Surgical techniques

The respective merits of a transperitoneal versus a retroperitoneal laparoscopic approach to the adrenal gland have been widely discussed in the literature. Most surgeons recognize the inherent difficulties of the reduced operating space with a retroperitoneal route, but espouse the advantages that come with avoidance of the peritoneal cavity and its risk of adhesions and trocar-site hernias. Importantly, retroperitoneal access allows for the rapid mobilization and early ligation of the adrenal vein (especially on the left side). This is particularly important for pheochromocytomas and malignant masses.

Published series have reported the need for increased surgeon experience with retroperitoneoscopy, but have not necessarily noted differences in overall complication rates [12–16]. It is important to note, however, that the retroperitoneal portions of some of these series were performed after the transperitoneal cases, making it difficult to differentiate between the importance of surgeon experience versus the importance of operative approach.

Nevertheless, there are currently no series that specifically address the benefits of one approach over the other when applied to laparoscopy of the adrenal gland. It does seem intuitive to recommend that each case should be planned on an individual basis, accounting for the size of the lesion, side of the pathology, patient's past surgical history, and experience of the surgeon.

Laparoscopic transperitoneal adrenalectomy (see Video 85.1)

The patient is placed in the lateral decubitus (45–60°) position, with the side of the lesion uppermost. This is the same position used in a flank approach for extirpative and reconstructive renal surgery. Pneumoperitoneum of 15 mmHg pressure is achieved either by open access or with a Veress needle before trocars are inserted (Figure 85.1). In general, three to four ports are used for this procedure.

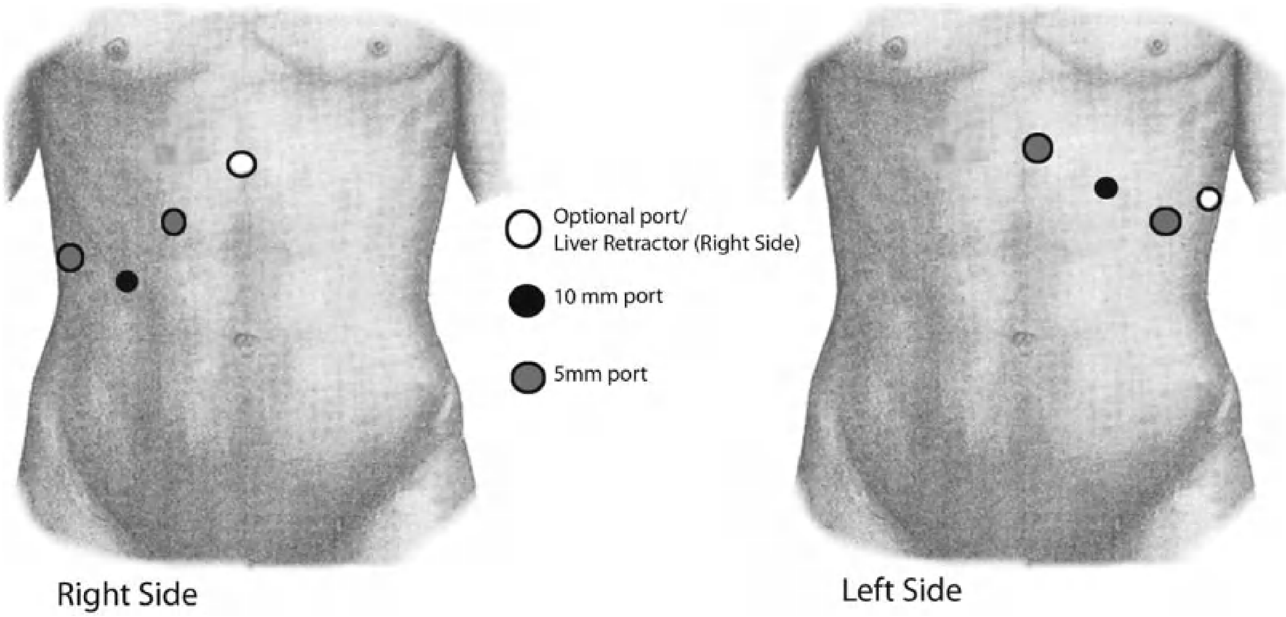

Figure 85.1 Port placement for transperitoneal laparoscopic adrenalectomy.

Right side

After adequate insufflation, the entire abdomen should be tympanic. Care must be taken during lateral insufflation to avoid intra-abdominal organ injury by the Veress needle (e.g. liver parenchyma), especially in the presence of possible adhesions. The abdominal cavity is initially inspected and any overlying adhesions are lysed. The exposure of the right adrenal gland depends on the adequate mobilization of the liver (Figure 85.2A). The triangular ligaments of the liver are incised, and the liver is gently retracted in the cephalad direction. The posterior peritoneum is incised close to the liver edge from the line of Toldt laterally to the inferior vena cava medially. The ascending colon and hepatic flexure are routinely mobilized. Gerota's fascia is then incised.

The upper pole of the kidney is identified, and the perinephric fat is dissected superiorly close to the inferior vena cava to expose the adrenal gland. The superior and anterior aspects of the adrenal gland are mobilized. Small blood vessels are controlled with electrocautery and laparoscopic clips. Dissection along the lateral border of the vena cava allows for identification of the right adrenal vein. Meticulous dissection is required to avoid tearing of the adrenal vein (Figure 85.2B). When the adrenal vein is isolated, laparoscopic clips are applied, with at least two clips on the vena cava side and one or two clips on the adrenal side. The adrenal vein is then sharply divided between the clips. The inferior and lateral aspects of the adrenal gland are mobilized. The Harmonic scalpel or LigaSure is a useful adjunct to facilitate dissection of the adrenal gland. The adrenal gland is dissected free from the surrounding structures. The specimen is placed into an organ entrapment bag before removal through one of the trocar sites (Figure 85.2C). The abdominal pressure is then lowered to 5 mmHg and the operative site is carefully inspected for bleeding before closure of the abdominal trocar sites. The 10/12-mm trocar sites require fascial closure with a 2-0 absorbable suture. A fascial closure device, such as the Puncture Closure Device (ConMed Corp, Utica, NY, USA), can be very helpful and avoids difficult and often blind suturing of the abdominal fascia. The skin is reapproximated with a subcuticular 4-0 absorbable suture. The surgical specimen is then sent to pathology for further examination (Figure 85.2D).

Left side

For a left adrenalectomy, the patient is placed in a right lateral decubitus position. Using endoscopic scissors or a Harmonic scalpel, the splenic flexure of the colon is incised along the line of Toldt. The dissection is continued superiorly to mobilize the spleen to the level of the gastric fundus. The upper pole of the kidney is exposed by freeing the posterolateral attachment of the lienorenal ligament in the direction of the diaphragm. The plane between Gerota's fascia and the pancreatic tail should be developed. The spleen is retracted superiorly and medially to expose the adrenal gland in the retroperitoneal space. This maneuver exposes the adrenal gland and will allow the dissection to begin in the correct plane. Subsequent dissection, specimen entrapment, and closure are similar to that described above for the right side.

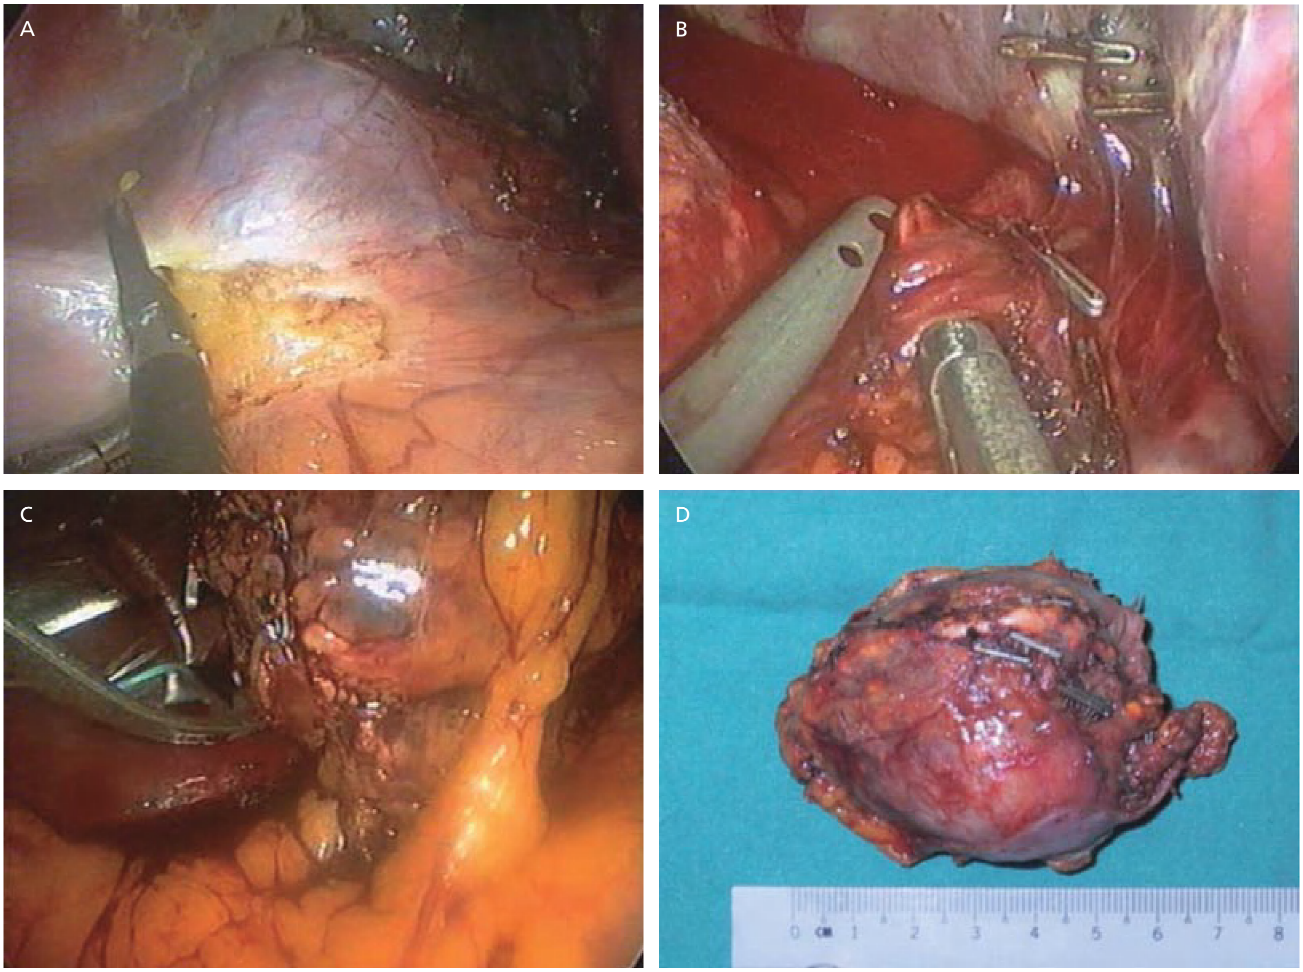

Figure 85.2 (A) Mobilization of a right adrenal tumor, (B) dissection of the right adrenal vein, (C) placement of the adrenal tumor in the entrapment sack, (D) adrenal tumor after removal; note clips on the adrenal vein.

Laparoscopic retroperitoneal adrenalectomy

Laparoscopic retroperitoneal adrenalectomy can be performed either using the lateral flank approach [13] or posterior lumbar approach [14]. The retroperitoneal LA avoids entering the peritoneal cavity and potential injury to the intra-abdominal organs. The lateral flank approach allows a more spacious working cavity, but a large tumor may obscure the surgical plane to the adrenal vessels. The posterior lumbar approach allows direct access to the main adrenal vascular supply before the gland is manipulated [15]. Depending on the surgeon's experience, a retroperitoneal approach may be used for obese patients and patients with previous abdominal surgery. However, the working space is smaller than the transperitoneal route, and this approach requires a longer learning curve.

In the more common lateral approach, the patient is placed in the full lateral decubitus position (90°) and secured in the standard fashion. The surgeon faces the back of the patient and the assistant stands on the opposite side. Initially, a small incision (2 cm) is made at the midaxillary line above the iliac crest. The incision is deepened until the retroperitoneal space is entered. The posterior pararenal space is developed using digital dissection. An adequate working space can be further developed using a commercially available balloon dilator. The pararenal space is expanded just outside Gerota's fascia. A 10/12-mm trocar is inserted and the posterior pararenal space is expanded with CO_2 gas insufflation at a pressure of 15 mmHg. The laparoscope is inserted and the other trocars are inserted under direct vision. If necessary, an additional 5-mm trocar may be placed above the iliac crest along the anterior axillary line to facilitate intraoperative retraction.

After insertion of all trocars, the insufflation pressure is then lowered and maintained at 10–12 mmHg. Gerota's fascia is incised widely in the cephalocaudad

direction. Caution should be taken to avoid inadvertent opening of the peritoneal membrane. Early entry into the perirenal fat to identify the adrenal gland should be avoided, as it can produce hemorrhage, which may obscure the operative field. The perirenal fat is dissected free from the surrounding structures, which include the diaphragm (superiorly), psoas muscle (posteriorly), and medially, the pancreas (left) or liver (right). In some cases, a laparoscopic ultrasound probe may be useful in identifying the adrenal gland.

The perirenal fat is dissected to expose the plane between the adrenal gland and upper pole of the kidney. Subsequent dissection of the adrenal gland, specimen entrapment, and closure is similar to that described above for the transperitoneal approach.

Robot-assisted laparoscopic adrenalectomy

The da Vinci Robotic Surgical System (Intuitive Surgical, Sunny Valley, CA, USA) consists of a robotic manipulator with three arms (two arms for surgical instruments and one for a central camera arm) and a remote console.

The patient is placed in the lateral decubitus (45–60°) position, with the side of lesion uppermost. The abdomen is then insufflated to 12 mmHg pressure before trocars are inserted (Figure 85.3). In general, four trocars (three robotic and one accessory) are used for this procedure, with an extra accessory trocar for liver retraction in the case of right-sided lesions. Besides changing robotic instruments as necessary and manipulating the suction, the assistant is also required to use the clip applier at the accessory port for division of the adrenal vein. The subsequent operative steps for robot-assisted LA are the same as for transperitoneal LA.

Postoperative care

In the recovery room, the nasogastric tube and urinary catheter may be removed. All fluids are begun on the day of surgery, if tolerated. Besides standard postoperative care, patients should be checked for electrolyte imbalance, especially in patients with Conn and Cushing syndrome. Adrenal insufficiency may also be seen in patients with Cushing syndrome, thus requiring steroid administration. Blood pressure should also be closely monitored with appropriate antihypertensive medications administered when required. In selected patients, a postoperative endocrinologic consultation may be required. Patients are typically discharged within 1–2 days after surgery if free of complications, and may resume normal activities as tolerated.

Results

Since 1992, many studies have reported the safety and efficacy of minimally invasive techniques for adrenalectomy. The results of contemporary series are summarized in Table 85.1. Published results from peer-reviewed journals have consistently shown that LA is both safe and efficacious. Furthermore, operative times have begun to rival those of open procedures as surgeons become more experienced with this technique and with laparoscopy in general.

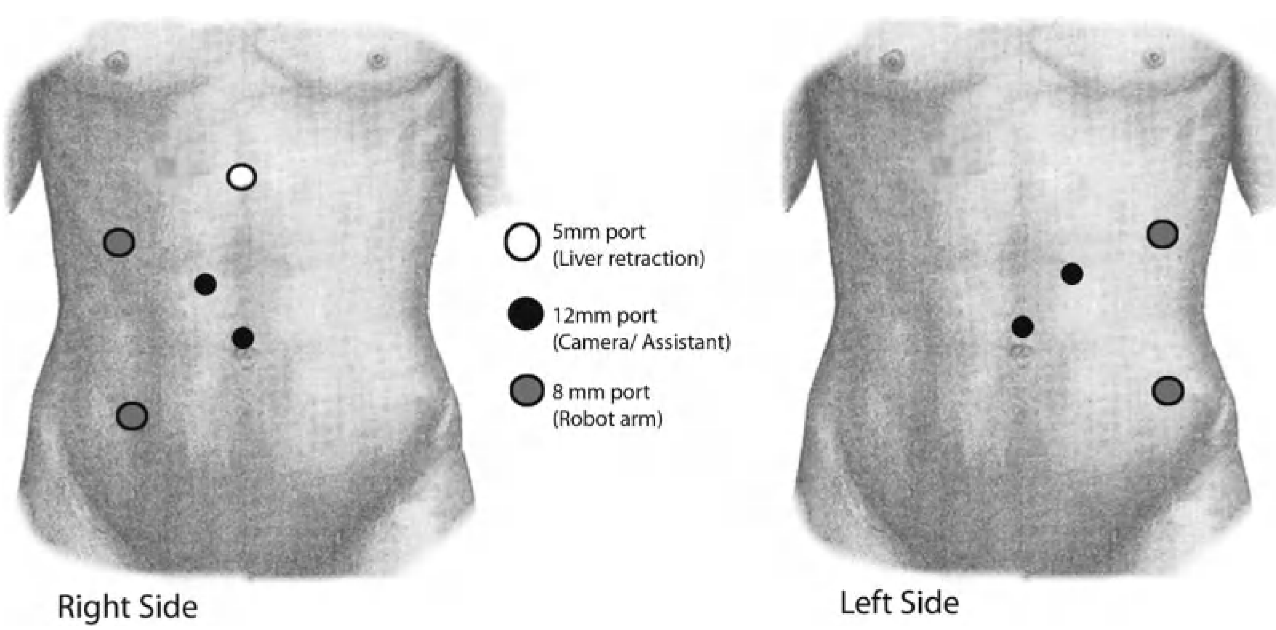

Figure 85.3 Port placement for robot-assisted laparoscopic adrenalectomy.

Table 85.1 Selected contemporary series of minimally invasive adrenalectomy.

Study	Year	Number	Approach	OT* (min)	EBL* (mL)	Hospital stay * (days)	Conversion to open surgery (%)	Intraoperative complications (%)	Postoperative complications (%)
Meria *et al*. [44]	2003	212	TP LA	102	85	3.6	14	4.7 (vascular injury, clip leakage)	10 (electrical myocardial ischemia, phlebitis, pneumonia)
Kazaryan *et al*. [45]	2009	242	TP LA	95	79	2	0	2.5 (vascular injury, minor injury to surrounding organs)	2.9 (pneumonia, hematoma)
Berber *et al*. [16]	2009	90	RP LA	138	25	1	0	0	2.2 (neuralgia)
Salomon *et al*. [46]	2001	115	RP LA	118	77	4	0.8	3.4 (vascular injury)	12.1 (hematoma, wound infection, parietal dehiscence, pneumonia)
Brunaud *et al*. [23]	2008	100	R-TP LA	99	–	6.4	5	3 (vascular injury)	3 (wound infection, pneumonia, hematoma, urinary tract infection)
Winter *et al*. [47]	2006	30	R-TP LA	185	–	2	0	0	7 (ileus, bronchitis, atelectasis)

OT, operative time; EBL, estimated blood loss; TP, transperitoneal, RP, retroperitoneal; LA, laparoscopic adrenalectomy; R-TP, robot-assisted transperitoneal.

At present, both surgeons and patients are eager to adopt a minimally invasive surgical approach. Recently, Park *et al*. published the outcomes of 3144 adrenalectomies [both LA and open adrenalectomy (OA)] in the USA that were performed from 1999 to 2005, a 20% stratified sample of all US nonfederal hospitals [17]. This study confirmed that LA was associated with lower complication rates, shorter hospital stay, and lower costs compared to the open approach. However, they did acknowledge that high-volume surgeons were twice as likely to perform LA, which may have a role in the 39% reduction in complication rate and a 29% reduction in hospital stay. The diffusion of robot-assisted laparoscopy may facilitate less experienced laparoscopists in adopting LA as the procedure of choice for adrenal lesions.

For functional adrenal lesions, numerous studies have reported favorable outcomes. In primary hyperaldosteronism, patients who underwent LA experienced fewer complications and a shorter hospital stay. Their blood pressure and hypokalemia were equally likely to improve [18, 19]. In patients with Cushing syndrome, the cure rate and operative and long-term morbidity were similar for the LA and OA approaches [20]. Patients with pheochromocytoma have also been successfully treated with LA [21]. Intraoperative hemodynamic values during LA for pheochromocytoma were comparable to those of traditional open surgery. Patients who underwent a laparoscopic procedure had a faster postoperative recovery [22].

Although LA has been accepted as the standard of care for benign adrenal lesions, its use in primary adrenal malignancy is still debated. Due to the rarity of primary adrenal malignancies, a randomized controlled trial comparing LA with OA is unlikely to be performed. However, several series reporting oncologic outcomes of LA and OA are available, and are summarized in Table 85.2. These data suggest that LA represents a safe and efficacious minimally invasive option in the management of noninvasive primary adrenal malignancy and should be considered as a viable option for patients with localized ACC.

Morbid obesity has been associated with increased operative times and with increased blood loss. However, Fazeli-Martin *et al*. reported that laparoscopic adrenal surgery is technically feasible in the markedly and morbidly obese patient. Compared with open surgery, it results in a quicker return of bowel function, less

Table 85.2 Selected contemporary series of open and minimally invasive adrenalectomy for primary adrenocortical carcinoma.

Study	Year	Number	Approach	Size (cm) *	Follow-up (months) *	Metastasis/recurrence	Overall survival (%)	Disease-free survival (%)
Moinzadeh *et al*. [48]	2005	6	LA	6	26	3 (42%) distant metastasis, 2 (28.5%) local recurrence	50	50
Gonzalez *et al*. [49]	2005	6	LA	5.5	28	5 (83%) distant metastasis, 3 (50%) local recurrence	20	0
Lombardi *et al*. [7]	2006	4	LA	5.9	23	0 distant metastasis, 1(25%) local recurrence	75	75
Hemal *et al*. [50]	2008	5	LA	>5	25	3 (60%) distant metastasis, 0 local recurrence	40	40
Porpiglia *et al*. [2]	2010	18	LA	9	30	4 (22%) distant metastasis, 2 (11.1%) local recurrence	94.4	66.7
Porpiglia *et al*. [2]	2010	25	OA	10.5	38	10 (40%) distant metastasis, 5 (20%) local recurrence	72	40
Terzolo *et al*. [51]	2007	130	OA	10	56.7	105 (78.9%) recurrence	50.7	19.2
Gonzalez *et al*. [49]	2005	133	OA	NR	28	56 (42%) distant metastasis, 46 (35%) local recurrence	37.6	13.5

*Reported as the mean or median according to the original paper.
LA, laparoscopic adrenalectomy; OA, open adrenalectomy.

analgesic requirements, shorter convalescence, and a reduced hospital stay [11].

A number of robot-assisted LA cases have been reported since 2001 [23–25], including a case of adrenocortical carcinoma [26] and a case of isolated adrenal metastasis treated by robot-assisted partial adrenalectomy [27]. Although robot-assisted LA has comparable perioperative outcomes with standard LA, the advantages have yet to be proven by controlled studies [28].

Complications

As with any laparoscopic surgical procedure, patient selection and the surgeon's experience are paramount. Judicious patient selection is probably the most important factor that can decrease the morbidity of a LA. Patients with relative or absolute contraindications to laparoscopic surgery should be considered for an open surgical procedure.

The size of the lesion has had a significant impact on outcomes. In general, tumors larger than 6 cm have an increased risk of malignancy. Larger lesions are also technically challenging, in part because they may distort the surrounding anatomy. This can lead to misinterpretation of the anatomic landmarks and increase the propensity towards serious, life-threatening complications. Patients undergoing adrenalectomy for large masses should also be counseled on the possibility of concurrent *en bloc* nephrectomy.

Different types of endocrinologic disorders can lead to disease-specific complications. Patients with Conn syndrome are likely to develop electrolyte abnormalities and require monitoring of blood pressure. Patients with Cushing syndrome may require postoperative steroid supplement. In patients with pheochromocytoma, close perioperative monitoring of blood pressure is essential. Cardiovascular complications, including stroke, may develop if appropriate measures are not taken.

To avoid complications, care should be taken during creation of the pneumoperitoneum. The Veress needle should be placed in proper position to avoid injury to the liver, spleen, and intestines. Alternatively, a Hasson technique for initial trocar placement can be used. During dissection, caution should be exercised to avoid injury to the surrounding structures such as the bowel and pancreas. These injuries should be recognized and repaired accordingly. When indicated, either a laparoscopic repair or open laparotomy should be performed.

Vascular complications are the most serious and may involve injury to the adrenal vessels, renal arteries and veins, and the inferior vena cava. Laparoscopic control of a vascular injury may be attempted with electrocautery or clips. In some cases, intracorporeal suturing may be used. When the patient is hemodynamically unstable or control is difficult, it is mandatory to proceed with open exploration to control the bleeding.

In the postoperative period, early ambulation is encouraged to reduce the risk of a deep vein thrombosis.

In selected patients, chest physiotherapy is required to prevent lung atelectasis. Postoperative shoulder pain is a common, though usually a self-limited, complication.

Current and future developments

Clipless and needlescopic adrenalectomy

Clipless LA obviates the use of clips during vascular control and involves the use of bipolar coagulation to control the adrenal vessels. Bipolar coagulation may be achieved using conventional electrocoagulators or modern energy-based devices, such as the LigaSure vessel-sealing system (Valleylab) or the ultrasonic coagulator (Harmonic scalpel). Misra *et al.* reported on a total of 10 patients undergoing successful uncomplicated clipless LA [29]. Bipolar coagulators can also be used for dissection, leading to less exchange of instruments. They also remove the requirement for individual dissection and isolation of blood vessels, minimizing avulsion and bleeding. However, the use of these instruments is limited by blood-vessel caliber and larger veins may not be adequately controlled by these devices alone.

Without the need for laparoscopic clipping instruments that require a 5-mm port, LA can be carried out using only needlescopic instruments. Needlescopic instruments are defined as those with a diameter of no more than 3 mm, therefore resulting in smaller incision than conventional 5–12-mm ports. Besides better cosmesis, needlescopic surgery may offer the advantage of reduced postoperative pain, hospital stay, and recovery time. Since the initial series of 15 patients by Gill *et al.* in 1998 [30], a large series of 112 patients was recently reported [31]. This series reaffirmed the safety and effectiveness of needlescopic LA for adrenal tumors less than 5 cm in size. It is important to note that needlescopic adrenalectomy should only be approached by experienced laparoscopic surgeons in carefully selected patients [32].

Laparoendoscopic single site

LESS is a novel minimal invasive surgical approach for the treatment of benign adrenal lesions. Through the development of new laparoscopic access ports (R-Port and Triport; Advanced Surgical Concepts, Ireland; Uni-X Single Port; PNavel Systems, Cleveland, OH, USA), several instruments can be inserted through multiple channels incorporated in a larger single port. Adrenalectomy is performed according to the steps of conventional transperitoneal adrenalectomy using articulated or bent instruments that permit triangulation intracorporeally despite the close proximity of several instruments (dissector, grasper, and scissors) via a single port. These instruments include roticulators (Covidien, Norwalk, CT, USA), Real Hand (Novare Surgical Systems, Cupertino, CA, USA); Autonomy Laparo-angle, laparoscopic needle drivers, and endoshears (Cambridge Endo, Framingham, MA, USA).

Although a number of studies have demonstrated the feasibility and improved cosmesis of LESS [33], other potential benefits (faster recovery, earlier return to normal daily activities, etc.) are yet to be determined. A recent case–control study by Jeong *et al*. did demonstrate that LESS is a safe technique with operative time, postoperative hospital stay, and complication rate comparable to the standard laparoscopic approach [34]. Long-term follow-up is required to establish its benefits.

While LESS is a highly challenging approach in which standard laparoscopic challenges are topped by the technical difficulties of lack of triangulation and instrumentation limits, it is an appealing alternative to conventional laparoscopy. In experienced hands, LESS has been shown to be feasible given appropriate patient selection.

Partial adrenalectomy

Partial adrenalectomy (PA) represents an organ-sparing approach to the adrenal gland whereby the tumor is removed leaving as much normal adrenal tissue as possible. This approach preserves a greater hormonal reserve and may avoid the need for hormonal supplementation following adrenalectomy. Current indications include bilateral benign adrenal lesions, solitary adrenal gland, or unilateral lesions in patients with familial syndromes, such as von Hippel–Lindau, familial pheochromocytoma or multiple endocrine neoplasia type IIA [27, 35]. PA has also been advocated in Cushing adenoma and sporadic pheochromocytoma with lesions less than 30 mm in diameter, as these tumors should be considered benign and do not require radical resection [36]. The indications for PA continue to expand as the importance of organ preservation is increasingly recognized.

PA may harbor an increased risk of recurrence due to the presence of residual adrenal tissue. Although recurrences can be rectified with additional procedures, the potential disadvantages of PA should be weighed against the risk of adrenal insufficiency and therefore quality of life.

The surgical technique of PA follows the steps of conventional LA for identification and dissection of the adrenal gland and tumor. The tumor is then excised using a Harmonic scalpel or LigaSure. These instruments allow for a minimal bleeding during transection of the adrenal parenchyma. Care should be taken to preserve the vascular supply of the remaining adrenal tissue, emphasizing the importance of a careful

dissection. Hemostatic agents (glues, Surgicel; Ethicon Endo-Surgery Inc) can be used for hemostasis when necessary. Employing electric current for hemostasis of the adrenal gland is not advised as it may result in hypertensive peaks intraoperatively.

Ablative techniques (radiofrequency/cryo/chemical)

Ablative techniques represent the new frontier of minimally invasive approaches and offer the benefits of low invasiveness and less technical challenges compared to conventional surgery. These advantages may translate into reduced morbidity as the procedure can be performed on an outpatient basis. Ablation techniques include radiofrequency ablation (RFA), cryoablation, and chemical ablation.

Ablation of adrenal neoplasms carries a significant risk of releasing a large amount of hormones rapidly into the bloodstream. Release of catecholamines can induce arrythmia or hypertension; thus, pretreatment with alpha- and beta-blockade is warranted.

Mayo-Smith *et al*. and Wood *et al.* have reported a series of 12 and eight patients, respectively, successfully treated with RFA for adrenal masses without major complications [37, 38]. RFA may require multiple applications, and contrast-enhanced imaging is required to ensure complete ablation of the treated adrenal lesion. The advantage of cryoablation over RFA is that the margins of cell death can be followed in realtime through visualization of the ice ball on CT. However, there have only been limited reports of adrenal cryoablation [39, 40]. Chemical ablation has seen relative success in the management of encapsulated hepatic tumors and has now been applied to adrenal neoplasm. Xiao *et al.* reported a 92.3% complete response rate for primary tumors in a large series of 36 patients [41].

The role of ablation in the treatment of adrenal tumors has yet to be determined and there have been suggestions that its greatest potential lies in the treatment of recurrent disease, small biochemically active tumors [42], as well as palliative care [43]. Ablative techniques are becoming increasingly popular in the urologic field with intensive basic and clinical research endeavors in place. Technologic advances in imaging and precise targeting of the lesions will likely enhance the appeal of these innovative approaches. However, until solid outcome data are mature, these techniques should be considered as experimental.

Conclusions

LA is safe, proven, and effective. LA currently represents the standard of care for treating patients with localized adrenal lesions. This is an advanced laparoscopic procedure and should be undertaken only by those with extensive laparoscopic experience. Technologic advances have allowed the introduction of robot-assisted LA, needlescopic, clipless, single-port LA, as well as percutaneous ablative techniques. These innovative techniques require longer follow-up and more data to assess their oncologic efficacy and perioperative outcomes. Therefore, they should be approached with caution and only be attempted if the surgeon is confident of adhering to the principles of oncologic surgery. These techniques strive towards reduced invasiveness and should not compromise the oncologic outcomes of the procedure.

We are currently witnessing a transition from conventional open to less and less invasive surgical approaches. The paradigm of open surgery for cancer is being continuously challenged and currently, with maturing laparoscopic experience, open procedures for adrenal lesions are being replaced by minimally invasive approaches with comparable efficacy.

CHAPTER 86

Laparoscopic and Robotic Reconstructive Surgery of the Ureter

Ioannis Varkarakis
Athens Medical School, Sismanoglio Hospital, Athens, Greece

Introduction

Conventional laparoscopic surgery is now well established for the management of a wide variety of procedures in operative urology, with well-documented advantages over open surgery [1]. Both extirpative and reconstructive procedures are performed routinely in clinical practice. A variety of ureteral pathologies, including ureteropelvic junction obstruction (UPJO), impacted ureteral calculi, ureteral strictures, and malignancies have been treated successfully with conventional laparoscopy. In this chapter we will review the laparoscopic and robotic surgical approach to pyeloplasty, ureterolithotomy/pyelolithotomy, ureterolysis, ureterovesical reimplantation, retrocaval ureter, repair of ureteral trauma, cutaneous ureterostomy, and ureterointestinal surgery.

When performing such operations, it must be kept in mind that ureteral surgery is one of the most challenging areas of urologic surgery. The small caliber and delicate nature of this organ make reconstruction particularly challenging. Intracorporeal suturing, especially in distal ureteral reconstruction in the confined working space of the pelvis when distal ureteral reconstruction, requires laparoscopic experience with free-hand suturing. As a result, reconstructive conventional laparoscopic procedures have not been widely adopted by community urologists, and are performed only in centers where advanced reconstructive procedures are carried out regularly with success equivalent to that of open surgery.

Robotics solves many of the technical complexities that are prohibitive in laparoscopic surgery, most notably precise cutting, intracorporeal suturing, and knot tying for reconstruction. Thus, robotic surgery may shorten the learning curve for laparoscopic reconstructive procedures for surgeons with no or minimal laparoscopic training [2, 3], making reconstructive ureteral laparoscopic surgery more widely available in centers with less laparoscopic experience. Despite cost acquisition issues, the da Vinci robotic system (Intuitive Surgical Inc, Sunnyvale, CA, USA) is being used by more and more urologists. As a result, the same variety of ureteral pathologies treated by conventional laparoscopy is now being treated by robot-assisted laparoscopy with equivalent success.

Good knowledge of ureteral anatomy, and proper patient selection and preoperative evaluation are similarly necessary for both conventional and robotic reconstructive laparoscopy.

Anatomic considerations

A comprehensive knowledge of ureteral anatomy is essential when performing either a pure or a robot-assisted laparoscopic procedure.

For surgical purposes, the ureter is divided into the abdominal or upper portion, and the pelvic or lower portion. The abdominal ureter extends from the kidney to the iliac vessels. It originates at the UPJ and courses along the psoas muscle before crossing the genitofemoral nerve at the level of the fourth lumbar vertebra. The gonadal vessels pass anteriorly over the mid upper ureter. The ureter extends toward the pelvic brim to cross the external iliac vessels on the right and the

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

common iliac vessels on the left. Once the ureter has entered the pelvis, it courses posterior and medial to the medial umbilical ligament and enters the detrusor muscle just posterior to the superior vesical artery. Important structures adjacent to the distal ureter include the vas deferens in the male, and the round ligament, uterine artery, and broad ligament in the female. These structures lie anteriorly and need to be divided to gain access to the distal ureter.

The upper ureter derives its blood supply from the renal artery, the mid ureter is fed by branches from the aorta and gonadal artery, while the lowermost portion of the ureter is served by branches of the common iliac, internal iliac, and vesical arteries. Once these vessels reach the ureter they course longitudinally within the periureteral adventitia, forming an extensive plexus. As such, ligation of much of the blood supply will not impact on viability in a healthy ureter.

It is important to recognize the normal relationship between the renal pelvis and the hilar vessels. The renal artery and vein are anterior to the renal pelvis, with the vein located most anterior. The renal artery divides into several branches, with the posterior being the most consistent and first to branch. The anterior branch divides into four segmental arteries (apical, upper, middle, and lower). Anomalous blood vessels can supply segments of the kidney. Lower pole vessels causing UPJO usually course anterior to the ureter.

Gerota's fascia is connected to the lateral parietal peritoneum by the lateroconal fascia. The space between this fascia and the posterior peritoneum is the anterior pararenal space, whereas the space dorsolateral to this fascia is the posterior pararenal space. This is the space entered during retroperitoneoscopy.

Of importance is the way the posterior peritoneum and the lateral peritoneal reflexion behave when the patient changes position. Moving the patient from a supine to a flank position displaces the peritoneal reflexion from the posterior axillary line anteriorly because of the downward movement of the colon. This increases the retroperitoneal space and decreases the potential of entering the peritoneal cavity when placing the trocars for retroperitoneoscopy.

The pelvic extraperitoneal space where the lower ureter will be found is the preperitoneal space caudal to the pelvic brim and between the parietal peritoneum and the fascia transversalis. Retzius' space is also considered a part of this space.

Patient selection

Patients with uncorrectable bleeding abnormalities, abdominal wall infection, generalized peritonitis; malignant ascites, and massive hemoperitoneum are at higher risk during laparoscopic surgery, pure or robot assisted. Large aortic and iliac aneurysms, and history of previous renal trauma or prior retroperitoneal or transperitoneal surgery can increase the difficulty of the procedure, but do not preclude laparoscopy, conventional or robot assisted, from being performed by a surgeon with laparoscopic expertise. Informed consent should always be obtained not only for the laparoscopic or the robotic procedure, but for an open procedure as well, in case conversion becomes necessary. The patient should know the procedure-dependent complications, as well as the complications involved with pure or robot-assisted laparoscopy itself.

Preoperative evaluation and preparation

A complete history and physical exam should always be recorded. Laboratory testing should be individualized, but urine should always be collected for microscopic analysis and/or culture. A blood type and screen should be available for all patients. No Aspirin or Aspirin-like compounds should have been taken within 5–7 days of surgery.

Radiographic and other specialized preoperative studies will be discussed for each surgical technique. X-ray films should be available and placed on the view box of the operating theater before the operation begins.

Pyelography should be the starting point in the evaluation of a patient with ureteral pathology. The intravenous or computed tomography (CT) pyelograms define the anatomy of the collecting system on the affected side. A diuretic nuclear renal scan is helpful in quantifying the degree of obstruction, if present, and documents the relative percentage of kidney function. The function of kidneys with high-grade obstruction is best assessed after the kidney is drained. A retrograde pyelogram is helpful in evaluating the ureter and delineating the length of obstruction if not seen on other imaging.

Operative preparation

Many of the preoperative steps are common for all conventional and robotic laparoscopic ureteral reconstructive procedures. Attention to these details will facilitate successful visualization of the ureter and minimize complications. A combination of ampicillin and gentamicin or a single dose of a third-generation cephalosporin is administered intravenously on arrival at the operating room. Pneumatic compression stockings are placed before induction of general anesthesia. A nasogastric or orogastric tube should be placed and the stomach emptied. The bladder should also be emptied using a Foley catheter. Placement of a ureteral stent before or during the laparoscopic procedure is at the surgeon's discretion.

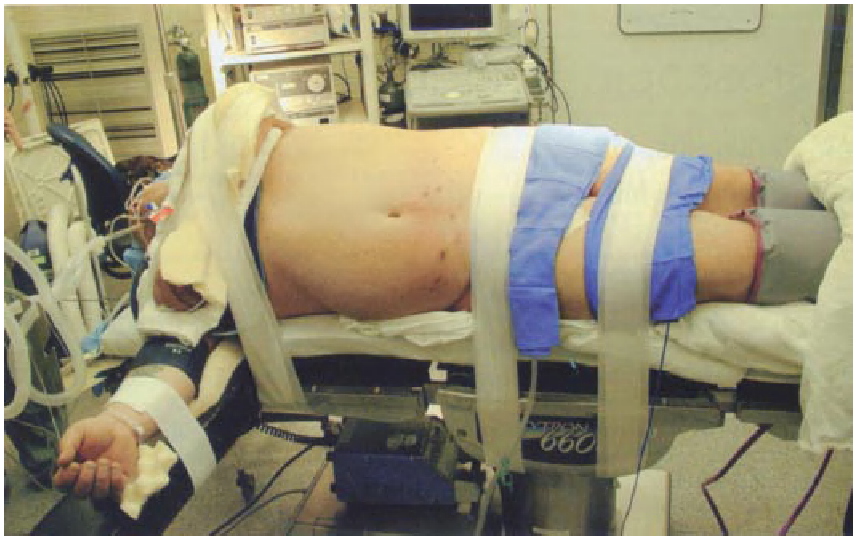

Figure 86.1 Modified lateral position of a patient undergoing conventional or robot-assisted laparoscopic reconstructive surgery of the upper ureter.

Positioning of the patient depends on the part of the ureter to be reconstructed, and is similar for both conventional and robot-assisted laparoscopy. For upper ureteral laparoscopic procedures, the patient is placed in a lateral or semi-lateral decubitus position. Some surgeons prefer the complete flank position or the 100° lateral semi-prone position, especially if the retroperitoneal approach is selected. This provides more space for trocar and instrumentation placement. Additional space can be obtained by breaking the operating table at the kidney level. A roll is placed behind the back to support the patient and the contralateral arm is padded and tucked alongside the patient (Figure 86.1). The ipsilateral arm is draped across the chest over egg-crate padding with the elbow gently bent cephalad. The ipsilateral shoulder is also rotated cephalad to move the arm away from the operative field, allowing maximal mobility of the laparoscopic instruments as well as of the robotic arms. The hips and legs are kept supine, with a pillow placed behind the knees and padding at the heels. Wide cloth tape is placed across the shoulder and hip to secure the patient to the table. The lower legs should be secured with tape or straps below the knees. The table should be test rolled prior to placing the drapes to be certain that the patient is secured to the operating table. The abdomen and exposed flank are shaved and prepared from the xiphoid to mid thigh, including the genitals in some cases.

Monitors for conventional laparoscopy are positioned at the upper third of the table across from the surgeon and assistant (Figure 86.2). During transperitoneal surgery, the surgeon is positioned on the abdominal side of the patient. During the retroperitoneal approach, the surgeon is positioned on the flank side of the patient.

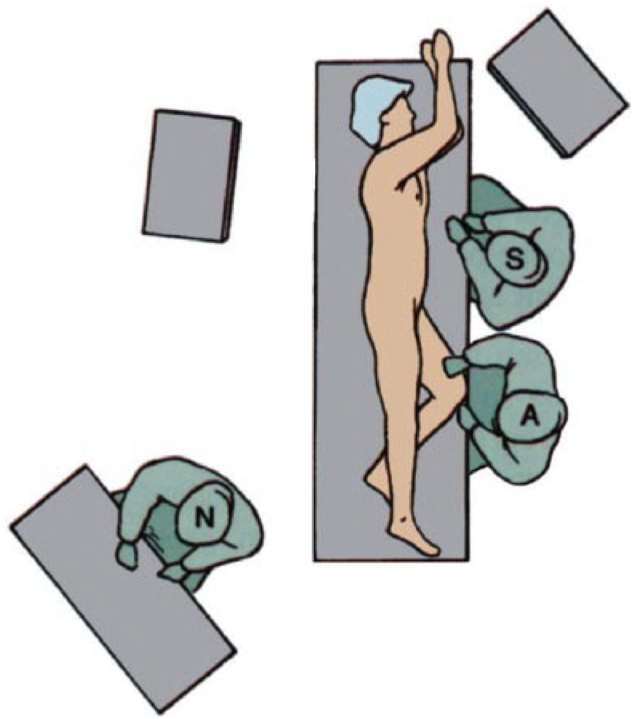

Figure 86.2 Positioning of operating room equipment and personnel for laparoscopic approach to right abdominal ureter. S, surgeon; A, assistant; N, nurse.

During transperitoneal robot-assisted laparoscopy for reconstruction of the upper ureter, the robot is placed on the ipsilateral side of the kidney being operated on (Figure 86.3). The assistant is situated on the other side. Although rarely used when the retroperitoneal approach is selected, the robot is docked from the abdominal side.

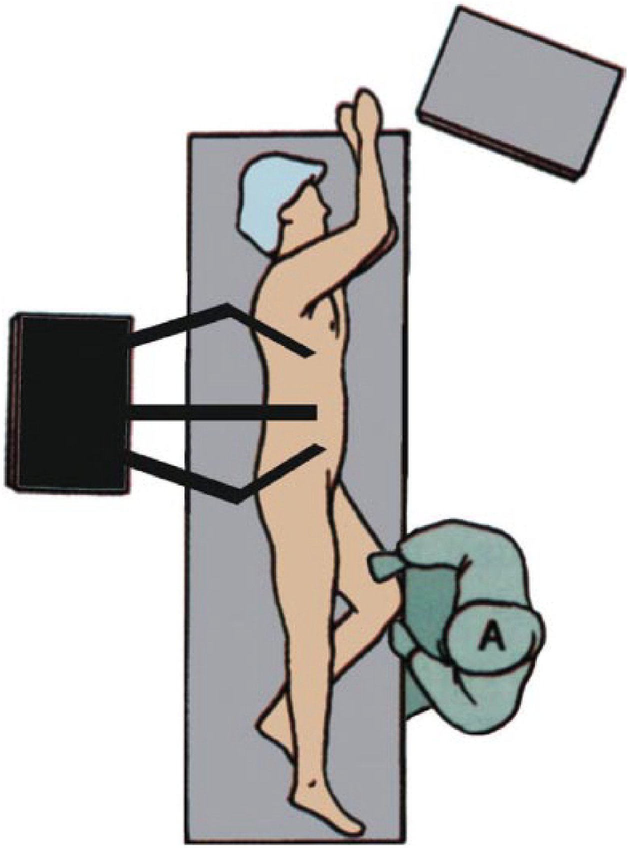

Figure 86.3 Positioning of robotic arms for robot-assisted laparoscopic approach to right abdominal ureter. A, assistant.

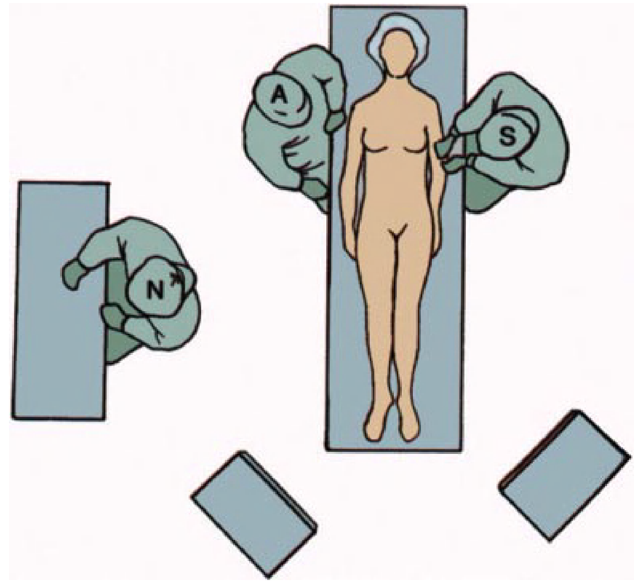

Figure 86.4 Positioning of operating room equipment and personnel for laparoscopic approach to right pelvic ureter. S, surgeon; A, assistant; N, nurse.

For conventional and robot-assisted lower ureteral laparoscopic reconstructive procedures, the patient is placed in the supine position. Each arm is positioned alongside the patient. Additional padding is placed along the arms, and under the knees and heels. For robot-assisted lower ureteral surgery, the patient's legs are placed in a low modified lithotomy position, comfortably supported using Allen stirrups (Allen Medical Systems, Acton, MA, USA). The patient is secured on the table with tape and special belts in case lateral flexion is needed. The monitors and robotic system are placed at the feet of the patient (Figure 86.4).

Access

Transperitoneal access

Port placement during conventional laparoscopy is individualized for each procedure. The trocar size chosen varies with each case and according to surgeon preference. During robot-assisted laparoscopy, trocar configuration may be very similar to that used for conventional laparoscopy; however, it must be kept in mind that two to three 8-mm nondisposable ports specifically designed for the da Vinci system are used, and should be placed at least a hand's length apart or a minimum of 9 cm away from each other to avoid collision problems with the working arms of the robot.

The upper ureter can most easily be accessed with the patient in the flank position. To establish a pneumoperitoneum, a Veress needle is introduced into the umbilicus. The peritoneal cavity is insufflated to a pressure of 15–20 mmHg. Usually three midline trocars are used for upper ureteral conventional laparoscopy: a 10-mm umbilical trocar, a 5-mm trocar one-third inferior to the xiphoid, and a 12-mm trocar half way between the umbilicus and pubis (Figure 86.5). Instead of the midline configuration, a trigonal or rhomboidal arrangement can be used (Figure 86.6). An additional fourth trocar may be used for assistance according to the surgeon's requirements. Trocars for robot-assisted laparoscopy are placed in V-shape fashion using two 8-mm trocars, one placed lateral to the rectus muscle at a level higher than the umbilicus and the other around 3 cm above and medial to the anterior superior iliac spine at a level lower than the umbilicus. A third 10–12-mm disposable umbilical trocar is used to accommodate the camera. An additional 10–12-mm midline port can be placed below the umbilicus in order to permit suction or quick suture exchange with the help of the assistant (Figure 86.7).

Trocar placement to approach the lower pelvic ureter is accomplished with the patient in a supine position and is the same for conventional and robot-assisted laparoscopy. A Veress needle is placed through the umbilicus, and pneumoperitoneum is established to a

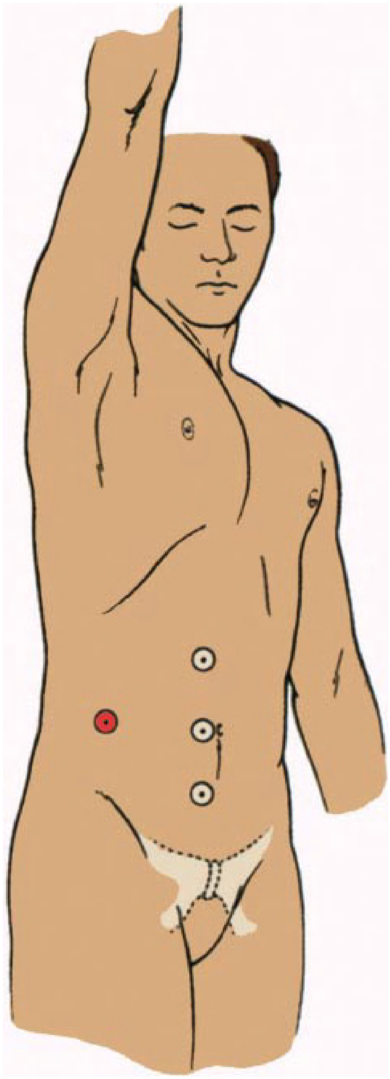

Figure 86.5 Linear port placement for conventional laparoscopic approach to abdominal ureter. The optional 5-10-mm port (red) is used for retraction.

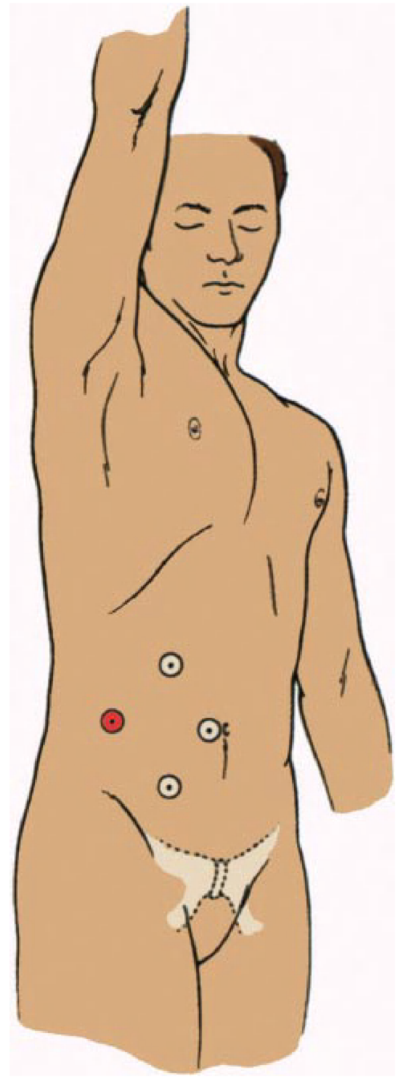

Figure 86.6 Trigonal port placement for conventional laparoscopic approach to abdominal ureter. The optional 5-10-mm port (red) is used for retraction (diamond-shaped configuration).

pressure of 15–20 mmHg. Initial trocar placement is performed through a semicircular 1-cm incision at the umbilicus, through which the camera will be inserted. One or two ports are positioned in each lower quadrant 2 cm medial to the corresponding anterior superior iliac spine (Figure 86.8). Again, during robot-assisted procedures two similarly placed 8-mm trocars, specific for the robot, are used. An additional 10–12-mm trocar can be placed suprapubically in order to permit suction or quick suture exchange with the help of the assistant. The configuration provides optimal access to the pelvic ureter from the iliac vessels to the ureterovesical junction (UVJ). In addition, if conversion is necessary, a shallow Pfannensteil incision can be made to include all three port sites. When approaching the entire ureter, a combination port placement is required (Figure 86.9).

All ports are secured in position with 2.0 Vicryl sutures. In case of scars due to prior surgery, either the Hasson cannula is preferred or the Veress needle is initially placed in a scar-free area of the abdomen, preferably the upper left or right quadrant.

Retroperitoneal access

With the patient in a flank position, the table is flexed, opening the costoiliac space. A 2-cm skin incision is made below the tip of the 12th rib. The flank muscle fibers are bluntly separated using the S-retractors. After the anterior thoracolumbar fascia is opened and access to the retroperitoneum is gained, finger dissection between the psoas muscle and the posterior side of Gerota's fascia is performed in order to create the initial

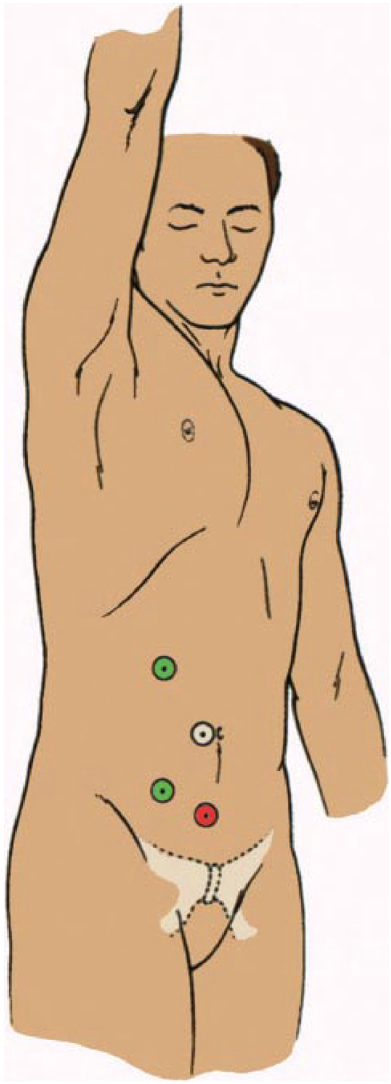

Figure 86.7 Port placement during robot-assisted laparoscopic approach to abdominal ureter. The green colored trocars represent specific robotic 8-mm trocars. The optional 5-10-mm port (red) is used by the assistant for retraction, suction or fast suture exchange. It is placed below the umbilical trocar or on the contralateral lower quadrant, depending on surgeon's preference.

space where the balloon dilator will be placed. Mobilization can be carried anteromedially in order to bluntly detach the lateral peritoneal deflection from the undersurface of the anterolateral abdominal wall to allow more space for the trocar placement. A trocar-mounted silicone balloon distention device [4] (Origin Medsystems, Menlo Park, CA, USA) is placed in the space made in the retroperitoneum. Installation of 800 mL of air in the balloon will create adequate space; 400 mL is sufficient in the pediatric population. For ureteral surgery, secondary balloon dilation caudal to the initial site of dilatation can be performed in order to have access to the middle and lower ureter.

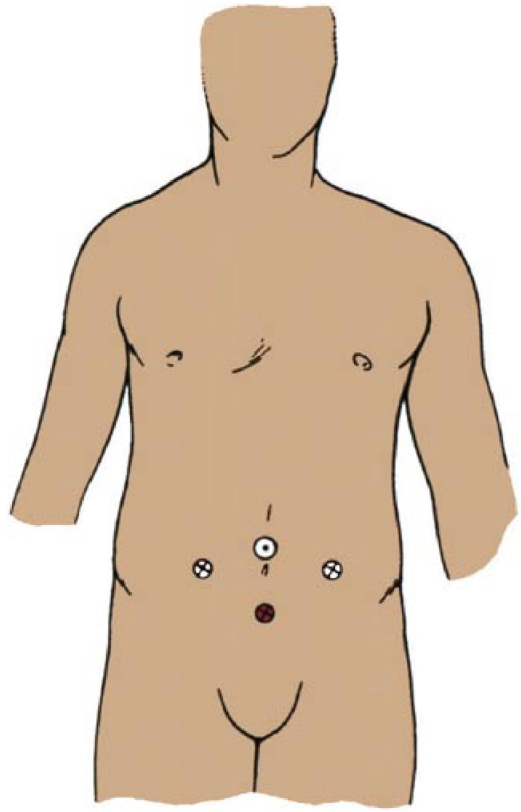

Figure 86.8 Port placement for conventional laparoscopic approach to the pelvic ureter.

Following balloon deflation and removal of the device, a 10-mm Bluntport trocar (Origin Medsystems, Menlo Park, CA, USA) is placed in the 2-cm incision. This trocar has an internal fascial retention balloon and an external foam cuff, which provides a better airtight seal. Pneumoperitoneum is achieved and the remaining ports are placed with a combination of direct camera guidance and manual control. Attention is needed not to enter the peritoneal space. The limited retroperitoneal space forces the trocars to be placed closer to one to another. This theoretically could be a problem for the robot-assisted approach since the robotic arms may collide.

Although individualized, the camera is placed through the 10-mm primary port, while a set of secondary ports are placed, one at the anterior axillary line, two to three finger breadths above the anterosuperior iliac spine, and the other at the lateral border of the paraspinal muscles along the inferior border of the 12th rib. A fourth auxiliary port can be placed along the anterior axillary line at the level of the costal border above the camera port (Figure 86.10). Robot-assisted laparoscopy is rarely used for ureteral reconstructive surgery and reports concern mostly the pediatric population [5]. The two 8-mm reusable ports are placed as described above for the conventional retroperitoneal approach.

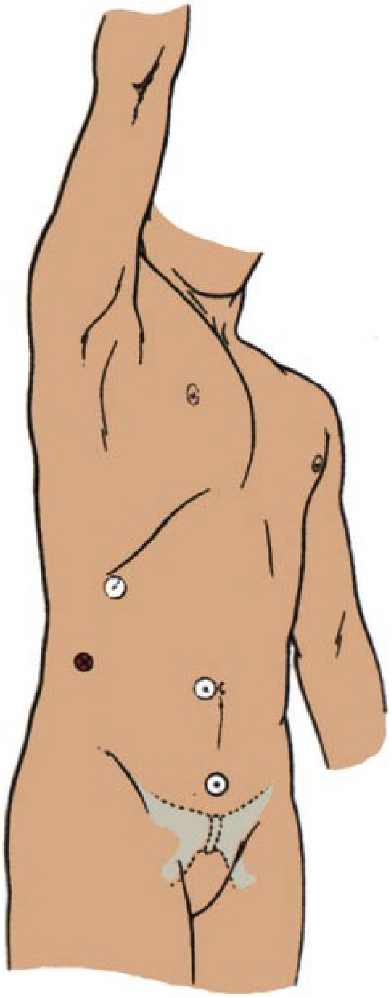

Figure 86.9 Combination port placement for access to the entire ureter.

Ureteropelvic junction obstruction

UPJO can be caused by a congenital intrinsic narrowing of the lumen or by external compression, usually by a crossing vessel. Preoperative evaluation includes a diuretic renogram and an intravenous pyelogram (IVP). Confirmation can be obtained at the time of surgery with a retrograde pyelography. Other diagnostic methods, such as CT angiography [6], endoluminal ultrasonography [7], and contrast-enhanced Doppler ultrasonography [8], can be used in case an obstructing vessel is suspected [9]. When laparoscopic repair is scheduled, the above-mentioned tests are not mandatory. Direct intraoperative observation obtained at laparoscopy will diagnose a crossing vessel.

Open pyeloplasty for the repair of UPJO was the standard treatment for several decades, with success rates of greater than 90% reported in several large series [10, 11]. The morbidity associated with a flank incision, however, has led to the development of minimally invasive retrograde and antegrade approaches to UPJ repair. Despite short hospital stay and rapid recovery, these endoscopic techniques have lower success rates, ranging from 65% to 87% [12, 13]. Success is even lower in the presence of a crossing vessel or a very dilated pelvis and poor renal function [14–16].

In 1993, laparoscopic pyeloplasty was introduced to reconstruct the UPJ under direct vision. The rational was to develop a procedure that had the advantages of minimal morbidity achieved with endourologic approaches while maintaining the high success rates of open pyeloplasty. This approach has been successful in a variety of pathologies, including patients with UPJO secondary to a crossing vessel, high ureteral insertion, large redundant renal pelvis, or those who failed a prior endoscopic repair.

Despite the presence of a large number of series of conventionally performed laparoscopic pyeloplasties,

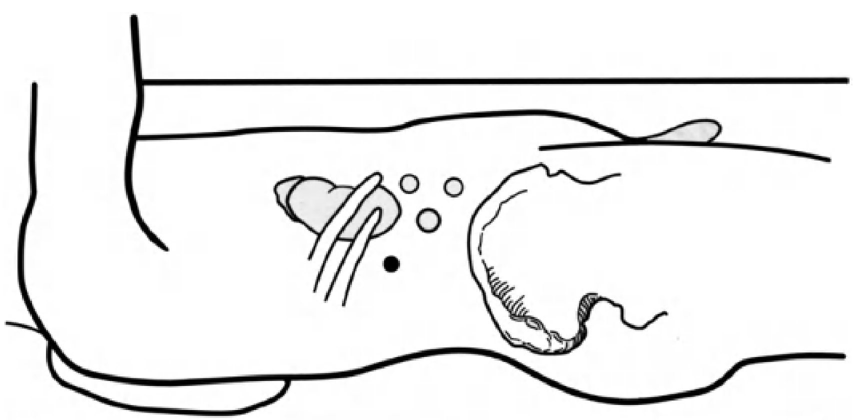

Figure 86.10 Port placement during retroperitoneal access to the abdominal ureter.

this procedure requires experience with laparoscopic free-hand suturing, which is quite a challenging task for a urologist located outside a high-volume laparoscopic center. The introduction of robot-assisted laparoscopy has made the task of laparoscopic suturing required for pyeloplasty easier to master. Therefore, robotic pyeloplasty is rapidly evolving as an equivalent therapeutic option for UPJO management.

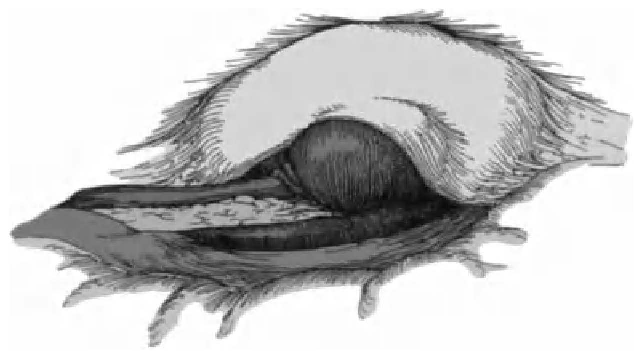

Figure 86.11 Incision of the peritoneal reflexion and medial mobilization to the colon to expose the right ureteropelvic junction.

Technique

Transperitoneal approach

The patient is positioned in a lateral position for access to the upper ureter (see Figure 86.1)., A retrograde pyelogram is obtained and, depending on surgeon preference, a 7F double pigtail ureteral stent is placed beforehand, or the stent is placed in an antegrade fashion during the laparoscopic procedure, using one of the laparoscopic ports or a 16G angiocatheter. It is important to select a stent that can extend from the bladder to the upper pole collecting system to prevent the curl of the stent from lying at the anastomosis, because this will make reconstruction more challenging. Port placement for access to the UPJ may be augmented by an additional 5-mm trocar placed in the anterior axillary line midway between the costal margin and the iliac crest (see Figures 86.5 and 86.6). Similarly, an additional port may be placed during robotic pyeloplasty at a similar location to that for conventional laparoscopy, to form a rhomboid configuration. Many robotic surgeons prefer to place the assistant's trocar at the midline or the contralateral side at a level midway between the umbilicus and pubis (Figure 86.7). All types of pyeloplasty can be performed with success both with conventional and robot-assisted laparoscopy. The most commonly performed type of laparoscopic pyeloplasty is the dismembered one (Anderson Hynes).

The surgical steps of a dismembered pyeloplasty are identical for conventional and robotic laparoscopy. The kidney and renal pelvis are identified lateral to the colon just beneath the peritoneum. The peritoneum overlying the kidney is incised from the upper pole to 4cm below the lower pole, and the colon is retracted medially. Positioning the patient laterally allows the colon to fall medially. The ureter can usually be identified by following the psoas muscle medially from the lower pole of the kidney (Figure 86.11). A sweeping motion with graspers perpendicular to the course of the ureter is used to bluntly dissect loose areolar tissue and identify the ureter. Dissection around the ureter distal to the UPJ should be minimized to preserve blood supply. In conventional laparoscopy, palpation of the indwelling ureteral stent aids in following the course of the ureter to the UPJ. During robot-assisted laparoscopy, palpation of the stent is not possible and its identification relies on optical cues. Care should be taken not to confuse the gonadal vessels and the ureter. If these vessels are impeding adequate visualization, they can usually be swept medially, but on occasion they need to be ligated and transected. Once the renal pelvis is identified, it should be dissected free to obtain adequate length to perform a tension-free repair. If a lower pole crossing artery is encountered, preservation is recommended to maximize future renal function. Alternatively, in patients with a thin mesentery, access to the UPJ can be obtained without reflecting the colon, but with a transmesocolic approach.

Once the UPJ is developed, scissors are used to transect the renal pelvis above the UPJ, and care should be taken not to spiral the incision or cut the ureteral stent if present. During robot-assisted pyeloplasty, several surgeons prefer to dock the robot at this point in order to use the robotic Potts scissors and continue the procedure robotically. Other surgeons prefer to dock the robot from the start and perform the entire procedure robotically, including identification and dissection of the UPJ. The proximal end of the stent is pulled from the pelvis after the anterior incision in the renal pelvis is completed. Spatulation of the ureter can be performed before or after the posterior wall of the pelvis is incised and the diseased portion of the UPJ removed. Care must be taken not to pull the stent out of the ureter during this maneuver. A reduction pyeloplasty can be performed at this time if necessary.

If an anterior lower pole vessel is encountered, it is transposed behind the renal pelvis. A 4-0 Vicryl suture is placed between the apex of the spatulated ureter and the dependent portion of the renal pelvis. The posterior row of sutures is then placed using interrupted or running 4-0 Vicryl sutures. If the stent is not present, it can be placed at this moment. Clamping the Foley catheter 1h earlier to distend the bladder may allow the ureteral stent to pass more easily into the bladder during

antegrade placement. In addition, indigo carmine is instilled into the Foley catheter to observe for backflow into the proximal ureter and confirm proper distal placement of the double-J stent if this in doubt. The proximal end of the ureteral stent is then repositioned in the renal pelvis, and the anterior row of interrupted or running sutures is placed. The excess pyelotomy incision above the repair is closed using a running 4-0 Vicryl suture (Figure 86.12). During robot-assisted pyeloplasty, haptic feedback is not present and care must be taken to avoid crush injury of the ureter from the robotic graspers and knot tearing due to secondary excessive force. However, suturing in particular is easier due to the infinite angulations the needle holders can make.

A 5-mm suction drain is placed through the lateral 5–10-mm port site. This drain is positioned near the posterior aspect of the reconstructed UPJ and secured externally to the skin with a 3-0 silk suture. The colon is replaced in its original position over the repair, and the procedure is concluded in a standard fashion.

The nasogastric tube is removed in the operating room, and the Foley catheter is taken out on the second postoperative day. The flank drain is removed when drainage becomes negligible, usually by the second postoperative day. If drain output increases, the Foley catheter is placed again for 48 h. A clear liquid diet is begun on the night of surgery and advanced as tolerated. Parenteral antibiotics are continued for 24 h. The ureteral stent is removed 3 weeks postoperatively. The repair is evaluated on an IVP 6 weeks after stent removal, and a nuclear renal scan is obtained at 3 months postoperatively.

Retroperitoneal approach

The patient is placed in a flank extended position. After developing the retroperitoneal space off the tip of the 12th rib and pneumoretroperitoneum established, two secondary ports are placed as described for access to the upper ureter (see Figure 86.10). An additional assistant trocar is optional, but usually necessary for robot-assisted pyeloplasty.

The retroperitoneal approach, although offering less space than the transperitoneal approach, has the theoretical advantage of identification of the ureter immediately after entering the retroperitoneal space. If the ureter is not readily seen, attention is paid to the hilar fat in order to identify the pulsating renal artery, and this will lead to the renal pelvis. Orientation in the retroperitoneal space can be difficult and this difficulty is enhanced when the computer-assisted system is used, since the surgeon is positioned remotely from the patient and has little sense of up and down. However, with experience, leaving the console to check instrument position will only rarely be needed.

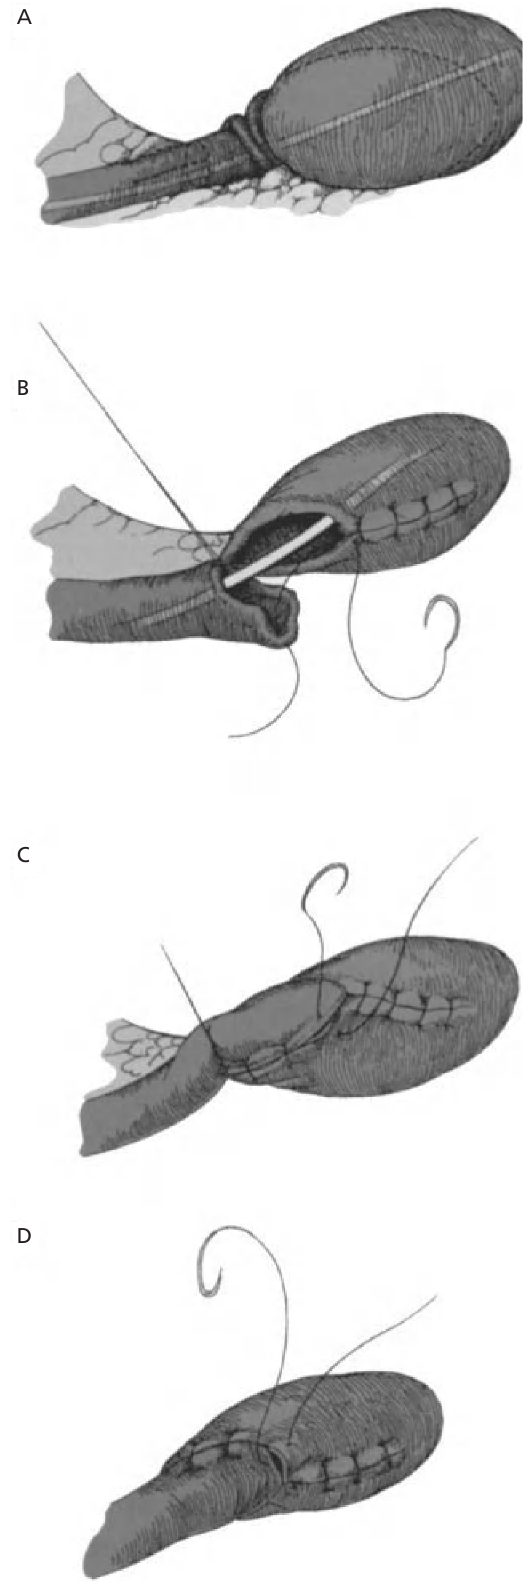

Figure 86.12 Reconstruction of a ureteropelvic junction by a lower pole crossing vessel. (A) Proposed incision. (B) Apex of spatulated ureter is anastomosed to the dependent portion of the renal pelvis after lower pole vessel posterior transposition. (C) Rotation of the ureter to provide access for posterior rows of interrupted sutures. (D) Completion of the anterior row of sutures to complete anastomosis.

Further ureteral dissection and pyeloplasty technique are performed as described previously for the transabdominal approach.

Results

Several large series of laparoscopic pyeloplasties demonstrate success rates equivalent to open surgery (Table 86.1) [17–24]. The benefits of avoiding the morbidity of a flank incision are clear. Compared to the open approach, the laparoscopic approach unequivocally offers a decreased need for analgesics, shorter hospital stay, and faster recovery. Complication rates are similar, if not lower, for the laparoscopic approach in several series. Most complications relate to the initial misplacement of the double-J stent or conservative treatment of anastomotic leakage. The procedure is almost never converted to open surgery and is performed with minimal blood loss in most cases. However, operative times are longer than those required for open surgery. This is attributed to the fact that laparoscopic suturing is challenging and requires experience to become time efficient, and the time taken for retrograde stenting must also be taken into consideration. With experience, overall operative times decrease.

Several large series of robot-assisted pyeloplasties have been reported (Table 86.2) [25–31]. Success rates are greater than 90% and comparable to those obtained with open surgery. Again compared to open pyeloplasty, analgesic requirements are less, hospital stay is shorter, and recovery is faster. Complications are similar. Average operative time is variable among studies, and robotic set-up time, technique used, and resident mentoring time may play a role. Several studies have compared the conventional to the robot-assisted approach (Table 86.3) [32–37]. Blood loss, analgesic requirements, complications, and success rates were similar between the two laparoscopic modalities. What is controversial is which modality is faster and has a shorter hospital stay. In the series by Link *et al.*, operating time for conventional pyeloplasties was shorter compared to that for robotic pyeloplasties; under the condition, however, that all procedures were performed by an experienced laparoscopic surgeon [33]. Contrary results were reported from the series in Innsbruck, where robotic pyeloplasty was faster than conventional pyeloplasty [34]. A meta-analysis of all reported comparative studies showed that robot-assisted pyeloplasty reduced operative time by 10 min only (P = .15), but was significantly associated with a shorter hospital time (P < .01) [38]. Data from this meta-analysis need further evaluation since the contributing studies included small numbers of patients, surgeons of varying experience, variable techniques, and no controls. Most authors consider that suturing during robot-assisted pyeloplasty is easier and faster. Obviously, this is less evident for a surgeon with large experience with laparoscopic suturing, but for the less experienced urologist the robot may facilitate the learning process.

Nevertheless, robotic pyeloplasty has several limitations and drawbacks. An assistant with laparoscopic skills is needed at the side of the patient for instrument exchange, retraction, and suture passage. There is no tactile feedback and more ports than in conventional laparoscopy may be needed, and as a consequence, the cosmetic result is inferior. Finally, the increased cost of robotic pyeloplasty is the most important disadvantage.

Several studies have analyzed the costs associated with the robotic systems, including their use for pyeloplasty [32, 33]. These costs include capital equipment costs, consumable costs, and calculated depreciation based on case volume and usage of capital equipment. In a financial analysis performed by Link *et al.*, robot-assisted pyeloplasty was 2.7 times more costly than laparoscopic pyeloplasty owing to longer operative time, depreciation of the robot, and higher running costs of consumables [33]. If depreciation were excluded, robotic pyeloplasty would still be 1.7 times more expensive, and only equivalent in terms of cost if laparoscopic pyeloplasty operative time was as long as 6.5 h. Bhayani

et al. essentially presented the same message when stating that for robotic pyeloplasty to obtain cost equivalence to laparoscopic pyeloplasty, the operating room time would have to be less than 130 min for more than 500 cases per year [32]. These data make robotic economics unfavorable and they are unlikely to improve even in high-volume centers. A similar study from the UK reported that robotic pyeloplasty was only 1.2 times more costly, despite the fact that hospital stay for robotic pyeloplasty was almost half as long as that for laparoscopic pyeloplasty (1.7 days vs 3 days) [39].

Most laparoscopic and robotic pyeloplasties are performed transperitoneally. This approach allows visualization of clear anatomic landmarks and has the advantage of a larger working space. The retroperitoneal approach is a viable alternative option and may offer an advantage when intraperitoneal adhesions or other pathology are anticipated. In a study by Zhang *et al*., retroperitoneal pyeloplasty was compared with the open approach [40]. The benefits of laparoscopy over open surgery were again evident. Less blood loss (10 mL vs 50 mL), less analgesic requirements (75 mg vs 150 mg of diclofenac), fewer complications (3.6% vs 7.5%), and a shorter hospital stay (7 days vs 9 days) were obtained, while success rates were equally high (98.2% vs 97.5%). Despite these excellent results, the reconstruction of the anastomosis may be harder with this approach, a fact reflected by the increased conversion rates when compared to transperitoneal pyeloplasties [41]. A prospective randomized trial by Shoma *et al*. comparing the two approaches during conventional laparoscopy found no significant differences between the outcomes and periprocedural parameters [42]. The only significant difference was the longer operative times necessary for the retroperitoneal approach. The limited working space may be a problem for robot-assisted retroperitoneal pyeloplasty as well. However, in the largest robot-assisted retroperitoneal pyeloplasty series presented by Kaouk *et al*., all 10 pyeloplasties were successfully completed with a success rate of 100% at a mean follow-up of 30 months [25]. The authors felt that the limited space was not a hindrance, especially with the robot positioned more cephalad.

Secondary pyeloplasty is more challenging due to fibrosis and has a higher failure rate. However, both conventional and robot-assisted laparoscopic pyeloplasty have been performed with low morbidity and can be used as an alternative to open pyeloplasty, with similar rates of success (around 85%) [17, 43, 44].

Other complicated cases of UPJ reconstruction have been performed both with conventional and robot-assisted laparoscopy [45], namely pyeloplasty in a horseshoe [46, 47] or pelvic kidney, UPJ reconstruction in the setting of a retrocaval ureter [48], pyeloplasty with concomitant lithiasis [49], and other upper urinary tract abnormalities. Bilateral pyeloplasties performed concurrently have also been reported [50].

Compared to other minimally invasive techniques, better success rates have been reported with laparoscopic compared to endoscopic techniques [51]. Improved results can be explained by the fact that both open surgery and laparoscopy can address a crossing vessel. When properly selected, endopyelotomy can achieve similar high rates of success. Endoscopic techniques have similar complication rates to laparoscopy, but usually a shorter hospital stay and operative time [52].

Pyeloplasty has been also performed with single-port surgery. Laparoendoscopy single-site (LESS) surgery, although in its infancy, has already found an application in both conventional and robot-assisted laparoscopic pyeloplasty (see Chapter 107). Series of single–port-only pyeloplasties only have not been reported yet. However, initial results from series comprising a wide variety of single-port urologic procedures confirm that pyeloplasty is feasible and safe [53, 54]. More information regarding success rates after appropriate follow-up is required.

Ureterolithotomy/pyelolithotomy

The development of extraperitoneal shock-wave lithotripsy (ESWL) and improvements in endoscopic, ultrasonic, laser, pneumatic, and electrohydraulic lithotripsy devices have greatly reduced the need for open stone extractions. A small number of patients, particularly those with large size or impacted stones, still fail these treatments and may require open removal. In addition, abnormal renal anatomy, such as a pelvic or horseshoe kidney or a double collecting system, may preclude endoscopic management or make it unfavorable. Open removal can also be indicated when there is a concomitant need for a reconstructive procedure such as a pyeloplasty.

Laparoscopic techniques have been used with success [55, 56] and may be considered for the uncommon patient in whom open stone surgery is considered when other first-line treatments (ESWL, endoscopy) fail. The use of robotic technology has helped with reconstruction. Laparoscopy has also been used to guide percutaneous nephrolithotomy (PCNL) in complex stone situations.

It is important to clearly define pelviureteral anatomy prior to the procedure by obtaining an IVP. If the distal ureter or pelvicalyceal system is not adequately visualized, a retrograde pyelogram can be obtained to rule out a concomitant stricture requiring reconstructive surgery.

Technique

With the patient in the supine position, an indwelling 7 F double-pigtail stent is placed under fluoroscopic

guidance immediately before the laparoscopic procedure. An open-ended ureteral catheter can be advanced to the level of the stone and used to assist in bypassing the stone with a wire. If a wire cannot be maneuvered past an impacted stone, then the external stent can be left in place and brought out through a council-tipped Foley catheter and secured via a Tuohy–Borst side-arm adapter. Alternatively, the stent can be placed intraoperatively in an antegrade fashion after stone extraction. Some authors are comfortable with not placing a stent at all if the ureterotomy is properly sutured [57].

The patient is positioned on the table according to the location of the stone. A stone located in the upper ureter or renal pelvis is approached with the patient in the lateral position, and port placement is similar to that for conventional or robot-assisted laparoscopic pyeloplasty, which in some cases is performed concomitantly (see Figures 86.5–86.7). For lower ureteral stones, the patient can be maintained in the supine position with the trocars as shown in Figures 86.8 and 86.13.

The line of Toldt is incised as previously described in the region near the stone. Alternatively, a mesocolic approach can be used, particularly in thin patients [58]. The retroperitoneal course of the ureter is exposed once the colon or sigmoid is reflected medially. Tilting the table away from the side of the stone allows the bowel to fall away from the operative field. Gentle grasping or transverse sweeping movements can be used to identify the position of the ureteral calculus, since the stone is usually palpable. During robot-assisted procedures, identification is based on optical cues only. Usually the ureter is visually dilated above the point of obstruction. Radiographic localization of the stone using fluoroscopy may be helpful if the stone is not readily apparent. Following the ureter cranially may lead the surgeon to the UPJ in cases of stones located in the renal pelvis.

Although impacted stones do not easily migrate cranially, it is wise to prevent this by using a double vessel loop. Once the stone is located, the ureter or renal pelvis is opened with laparoscopic or robotic scissors. Some authors propose using a pointed diathermy hook, and the use of electrocautery has been shown not to affect ureteral tissue healing[59]. The incision is made just large enough to allow the stone to be removed intact. By gently milking the ureter, the stone can be delivered through the incision (Figure 86.14 and 86.15). Alternatively, forceps or a rigid grasper can be used to detach the impacted stone from the mucosa. Every attempt should be made to remove the stone in one piece. An organ entrapment sac may be used for large stones. Stone fragments are retrieved using baskets through a flexible auxiliary cystoscope.

An internal stent should be positioned in patients in whom a preoperative stent could not be passed beyond the stone. This is accomplished by passing a wire through the external stent and guiding it under direct vision up the proximal ureter. The external stent is removed and an indwelling double pigtail stent can be passed over the wire. Correct positioning should be verified cystoscopically or radiographically. Alternatively, a

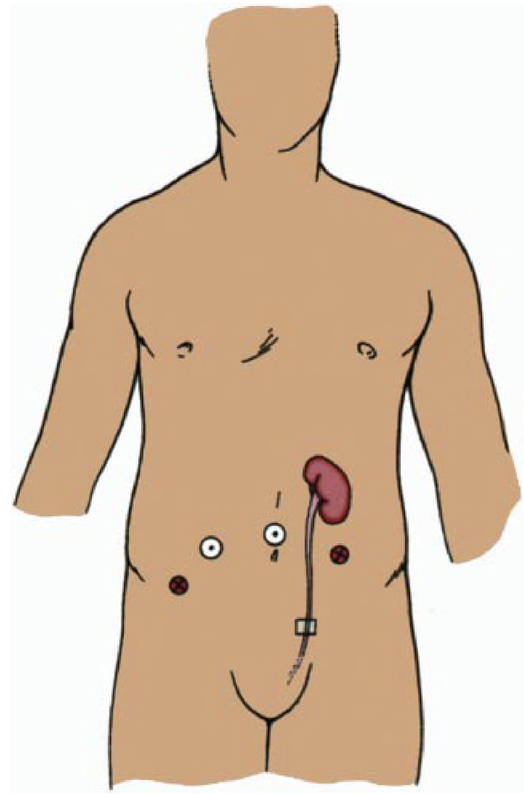

Figure 86.13 Port placement for laparoscopic ureterolithotomy of the left lower ureteral stone. The 10-mm port should be placed contralateral to the side to be approached.

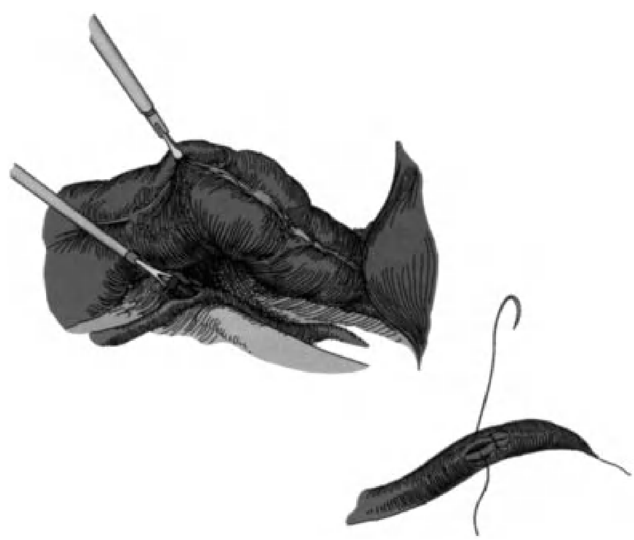

Figure 86.14 Stone is delivered through a ureteral incision and the ureterotomy is closed with interrupted sutures.

stent can be placed in an antegrade fashion, as described for pyeloplasty.

The ureterotomy can be loosely reapproximated over the ureteral catheter using interrupted 4-0 Vicryl sutures. Alternatively, if the incision is less than 1 cm, it may be left open to heal over the stent. A urethral catheter is placed. A retroperitoneal suction drain is placed in a fashion similar to that described for laparoscopic pyeloplasty.

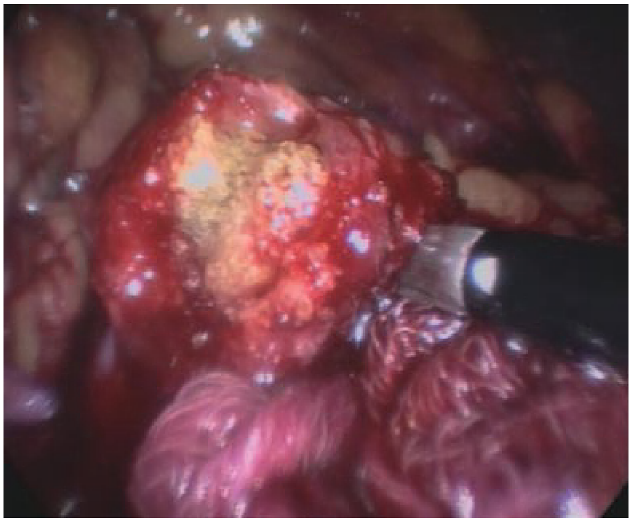

Figure 86.15 Delivery of the impacted middle ureteral stone during transperitoneal laparoscopic uereterolithotomy.

For the retroperitoneal technique, the patient is in the flank position. A small incision is made at the tip of the 12th rib, through which the retroperitoneal space is balloon dissected. If the stone is located lower than this, the balloon dissector is repositioned so dissection continues more distally. The first port is placed in this incision. Two more ports are placed with a combination of direct vision and manual guidance. Port location for both conventional and robot-assisted laparoscopic upper ureteral stone management is similar to that proposed for pyeloplasty (see Figure 86.10). After balloon dissection, the stone location is usually evident and little further dissection is needed to reach the bulging ureter. The ureter again can be used as a guideline to reach the renal pelvis. The following steps for removing the stone are similar to those followed in the transabdominal approach. For lower ureteral stones, the patient is placed in a supine position with the trocars placed as described for any case involving lower ureteral surgery (see Figure 86.8).

Once drainage becomes minimal, the drain should be removed. The stent is removed 4–6 weeks postoperatively. Follow-up study includes an IVP at 3 and 6 months after stent removal.

Results

A laparoscopic approach is rarely (1.1%) [60] needed in patients requiring stone removal. Experience with laparoscopic ureterolithotomy is adequate (Table 86.4) [59, 61–65]. Stone-free rates are high and complication rates

Table 86.4 Results of laparoscopic ureterolithotomy series.

low. The most common complication reported is prolonged urinary leak, especially when the lithotomy has been left open and is not sutured.

Laparoscopic ureterolithotomy can be performed with success using either the transperitoneal or retroperitoneal approach. In a comparative study of 35 patients, the retroperitoneal approach was associated with significantly longer operative times (102 min vs 75 min) due to the longer time taken to access the operative field and suturing [66]. This reflects the difficulties that may be experienced if the surgeon is not familiar with this approach. No statistical differences were observed for any other parameters or success rates. However, with experience the retroperitoneal approach can be equally efficient. In a study evaluating the learning curve of retroperitoneal laparoscopic ureterolithotomy, the first 20 patients undergoing this procedure were compared with the next 20 [67]. Operative time significantly decreased (120 min vs 65 min), as well as complication (15% vs 0%) and conversion rates (10% vs 0%). Similarly excellent results have been obtained with retroperitoneal pyelolithotomy. In a study comparing retroperitoneal and transperitoneal pyelolithotomy, stone-free rates and clinical outcomes were similar; however, the retroperitoneal access was associated with a shorter operative time, a faster time to oral intake, and a shorter hospital stay [68].

Laparoscopic stone removal can also be used for large recurrent ureteral stones previously treated with open ureterolithotomy, although dissection may be harder [69]. Stenting during laparoscopic ureterolithotomy and pyelolithotomy is not necessary if adequate suturing is performed; however, prolonged urine leak can be anticipated [70].

Laparoscopic pyelolithotomy is rarely performed due to the high effectiveness of PCNL. However, when concomitant pyeloplasty is required, a laparoscopic approach is well established. Before UPJ repair, stones are extracted through a small pyelotomy that is incorporated into the final pyeloplasty incision. Stone-free rates are high (>80%) [71, 72]. Large pelvic and partial staghorn stones have been successfully treated with laparoscopy; however, stone-free rates for complete staghorn stones are inferior. Pelvic stones in ectopic kidneys can be retrieved laparoscopically as well [73, 74].

Laparoscopic ureterolithotomy has been compared to other minimally invasive techniques. In studies comparing laparoscopic ureterolithotomy to ureterolithotripsy for stones larger than 1.5 cm, operative time and hospital stay were significantly longer for laparoscopy and there were more complications, but stone-free rates at 4 weeks postoperatively were better (100% vs 77.5%) with this approach [75, 76]. In a randomized study comparing ureterolithotripsy, percutaneous lithotripsy, and laparoscopy for upper ureteral stone removal, stone-free rates at discharge were 56%, 90%, and 64%, respectively [77]. At 3 weeks postoperatively, success rates were 88%, 86% and 76%, respectively. However, prolonged drainage was seen in 18% and 16% in the percutaneous and laparoscopic groups, respectively. Ureteroscopy was associated with the least morbidity compared to the other two approaches.

When compared to the open approach, postoperative pain and hospital stay were significantly less with laparoscopy, while operating times, estimated blood loss (EBL), complication and success rates were similar [78].

When comparing laparoscopic pyelolithotomy with PCNL, operative times were significantly longer for laparoscopy (129 min vs 75 min), but complications (12% vs 18%), hospital stay (6.5 days vs 5.6 days) and stone-free rates (88% vs 82%) were similar [79]. When evaluating all these comparative studies, their retrospective nature, the limited number of patients involved, and the diversity of stone size, location, and indications must be kept in mind. Experience among various authors and instrumentation between institutions may vary significantly, influencing final outcomes.

Experience with robotic laparoscopic ureterolithotomy/pyelolithotomy is limited, but results are encouraging. This procedure is feasible and safe given the reconstructive capabilities of the robotic system. This technique is in its early stage of implementation and randomized trials comparing robot-assisted outcomes with other minimally invasive techniques are needed to define clinical efficacy as it pertains to subsets of patients with variable stone size, location, and consistency. Operative times from small series of 6–13 patients vary from 158 to 315 min, while conversion was needed only once. Complications were not reported and stones were removed in all but two cases, including a complete staghorn stone [80, 81].

Laparoscopic management of stones can be used in association with endoscopic techniques. PCNL or ureterolithotripsy have been performed under laparoscopic guidance [82, 83].

Laparoscopic ureterolithotomy has been also performed with single-port surgery. LESS, although in its infancy, has already found an application in conventional laparoscopic ureterolithotomy (see Chapter 107). Series of single-port only ureterolithotomies have not been reported yet. However, initial results from series comprising a wide variety of single-port urologic procedures confirm that stone management is feasible and LESS is safe [84]. More information regarding success rates after appropriate follow-up is required.

Ureterolysis

Retroperitoneal fibrosis is an inflammatory condition of the retroperitoneum that occurs as either a primary (idi-

opathic) form or secondary to conditions such as inflammatory bowel disease, endometriosis, radiation therapy, neoplasm, vascular aneurysms, or drug therapy (i.e. methysergide) [85]. The goals of ureterolysis include relief of ureteral entrapment, preservation of renal function, prevention of recurrent obstruction, and diagnosis of underlying pathologic causes.

To evaluate the extent of retroperitoneal disease and to rule out the possibility of occult malignancy, a CT scan of the abdomen and pelvis with oral and intravenous contrast must be obtained. An MRI can alternatively be ordered. A search for malignant conditions in adult men should include a digital rectal examination, stool guaiac test, prostate-specific antigen (PSA), and a chest X-ray film. Adult women should have a pelvic examination, stool guaiac test, breast examination, mammogram, and chest X-ray film. The addition of a erythrocyte sedimentation rate may provide a tool for following the activity of the inflammatory process. An IVP should be obtained to define the degree of medial ureteral displacement. Renography should be performed to assess the residual function and degree of obstruction on the affected side. A retrograde pyelogram just prior to the laparoscopic procedure may also be helpful to delineate the entire course of the ureter and rule out possible distal ureteral strictures.

Technique

After placement of an indwelling ureteral stent, the patient is positioned in a fashion similar to that described for conventional or robot-assisted laparoscopic pyeloplasty (see Figures 86.5–86.7). A supine position may be used if both ureters are involved. The table can be rotated to allow the bowel to fall out of the operative field. An exdwelling ureteral stent or lighted stent helps in identifying the course of the involved ureter. In experienced hands, an indwelling ureteral catheter is usually sufficient and it should be of sufficient length to allow lateral displacement of the ureter.

A pneumoperitoneum is established and trocars placed as illustrated in Figures 86.5–86.7 to allow access to the upper ureter. An additional 5-mm port may be placed in the anterior axillary line midway between the costal margin and iliac crest. This port aids in retraction during dissection of the ureter. This port alternatively may accommodate the fourth robotic arm through an 8-mm special trocar when robot-assisted surgery is performed.

Surgical steps are identical for conventional and robot-assisted ureterolysis. With the use of grasping forceps and dissecting scissors, the colon is retracted medially and the peritoneal reflection incised across the iliac vessels, ending distal and medial to the medial umbilical ligament. The incision is then extended proximally to the hepatic flexure on the right or splenic flexure on the left. A sweeping motion brings the colon medially and exposes the psoas muscle. It is important to remember that the fibrotic process may retract the ureter over the great vessels. The ureter should be first identified in the portion uninvolved by the fibrotic process. This is usually in the area medial to the medial umbilical ligament near the bladder or proximally in the region of the UPJ.

The assistant or the fourth robotic arm retracts the periureteral tissues laterally, while the surgeon develops a window around the ureter. A right-angled forceps is used to pass a 4-inch piece of umbilical tape around the freed segment of the ureter. The ends of the umbilical tape are fastened together using a single 9-mm clip. This maneuver facilitates retraction of the ureter to aid in dissection. Care must be taken not to pull too vigorously to avoid avulsing the ureter. This is particularly true for robot-assisted laparoscopy due to the lack of tactile feedback.

Every attempt should be made to rule out malignancy as a cause of the obstruction. Biopsies of periureteral tissues must be taken using biopsy forceps and specimens should be sent for frozen and permanent sections.

A combination of blunt and sharp dissection is used to shell the ureter out of the fibrotic process. To prevent compromise of the ureteral blood supply, cauterization should be used with great caution. The gonadal vessels can be involved in the inflammatory process and should be dissected off the ureter. If necessary, they may be clipped and transected. The dissection is continued until the ureter is freed from the renal pelvis to below the fibrotic process.

Once the ureter is free, it is necessary to isolate it from the fibrotic process. The medial and lateral cut edges of the peritoneum are reapproximated after the ureter is transposed into the peritoneal cavity. A hernia stapler or suture placement can be used to reapproximate the incised peritoneal edges (Figure 86.16). Using an Endo-GIA stapler inserted through the umbilical port or another 12-mm assistant port to split the omentum, an omental wrap can be created. The tissue is used to create a sleeve that can be positioned around the ureter and secured to itself using 9-mm clips or 3.0 Vicryl sutures. Drains are not necessary if the procedure was uncomplicated.

An IVP is performed 2 weeks following surgery, at which time the ureteral stent is removed. Follow-up radiographic studies (IVP and diuretic renal scan) are then obtained at 3, 6, and 12 months postoperatively. Regular activities are resumed after removal of the stent.

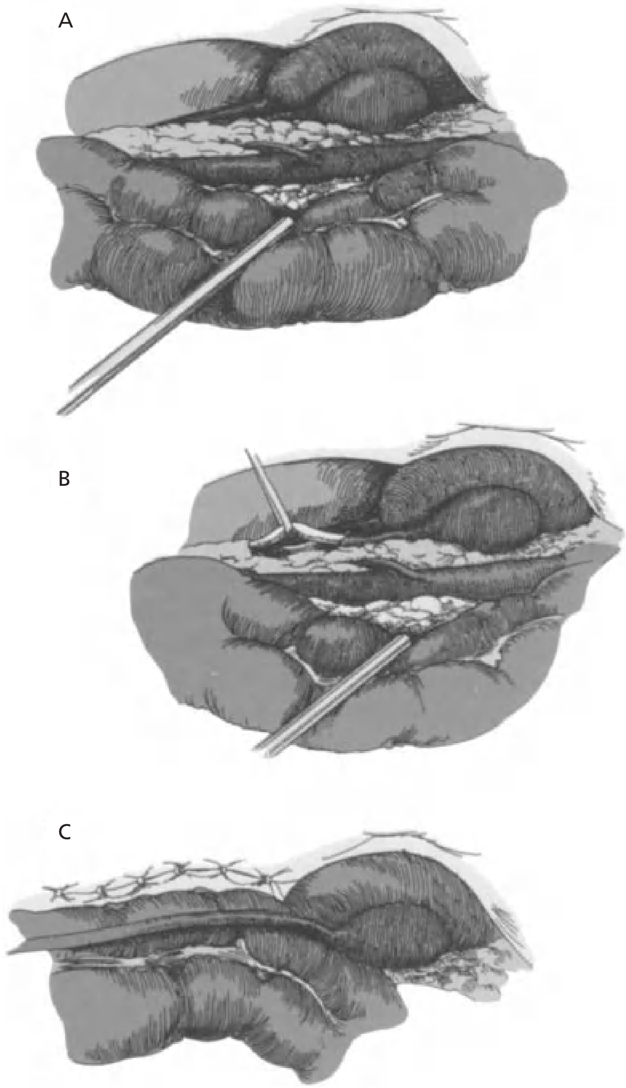

Figure 86.16 (A) Incision of the peritoneum and medial retraction of the colon to expose retroperitoneal fibrosis with the encased right ureter. (B) Umbilical tape aids in retraction for dissection of the ureter. (C) Ureter is intraperitonealized and the cut edges of the peritoneum are reapproximated.

Results

Idiopathic retroperitoneal fibrosis is rare and medical management with steroids, immunosuppressants, tamoxifen, and other drugs is often successful. Thus, large series of laparoscopic ureterolysis are scarce.

In the largest series, 34 patients undergoing laparoscopic ureterolysis were compared to 36 patients undergoing an open procedure [86]. Operative times, EBL, hospital stay, complication and success rates were similar between the two groups; however, in a subgroup analysis performed for patients with primary retroperitoneal fibrosis, those undergoing the laparoscopic approach had a significantly shorter hospital stay (3.4 days vs 10.8 days) and were significantly less likely to require a transfusion (3.7% vs 13.7%). Of note is the fact that ureterolysis can be a very challenging procedure and therefore conversion was required in 17.6% of this cohort. Injury to adjacent vessels and the ureter are the most common complications.

Due to the difficulty of this procedure, hand-assisted laparoscopic ureterolysis has been used with success. In a series of five patients, one minor intraoperative ureteral injury was noted and no postoperative complications occurred. Mean operative time was 259 min, while success after 22.4 months was 90%. The authors considered this approach was easier and faster than pure laparoscopy [87].

Robot-assisted laparoscopic ureterolysis has been reported, but experience is small. In a series of five patients mean operative time was 220.5 min for unilateral ureterolysis and 390 min for bilateral ureterolysis. Mean EBL was 33.5 mL, mean hospital stay was 2.8 days, and after a follow-up period of 5.6 months success was 100% [88]. Thus, robot-assisted ureterolysis and omental wrap is feasible and safe, and compares favorably to the pure laparoscopic technique. In a comparative study from the same institution, five patients underwent laparoscopic ureterolysis and five robot-assisted ureterolysis [89]. Mean operative times for bilateral and unilateral laparoscopic ureterolysis were 509.0 min and 110 min, and the mean EBL was 362.5 mL and 50 mL, and for bilateral and unilateral robot-assisted ureterolysis, 390 min and 220.5 min, and 25 mL and 35.5 mL, respectively. With a mean follow-up of 15.6 months, 90% of all patients were asymptomatic and 86.7% of renal units had no signs of obstruction on imaging. No meaningful differences were deduced from this small series of patients.

Long-term success can be excellent. After 37.5 months of follow-up, success remained at 100% for six patients undergoing laparoscopic ureterolysis [90].

Although bilateral ureterolysis in one setting is possible, performing prophylactic contralateral ureterolysis is under debate. In Fugita *et al*.'s series of 13 patients, no patient with unilateral disease developed contralateral ureteral involvement at a mean follow-up of 23 months, supporting ureterolysis only when ureteral involvement is present [91].

Ureterovesical reimplantation

Open ureteral reimplantation is performed in children for vesicoureteral reflux. In adults, a refluxing anastomosis is usually performed for the treatment of distal ureteral strictures or endometriosis where endoscopic therapy is inappropriate or has failed. Strictures can be the result of a ureteral injury occurring usually during gynecologic surgery or secondary to impacted ureteral stones treated with multiple ureteroscopies and pro-

longed ureteral stenting. In all cases, stricture length and location should be determined with appropriate antegrade and retrograde studies. In addition, functional studies should be obtained if there is a question of decreased renal function. Reimplantation is also performed after distal ureterectomy for lower-third ureteral tumors when a decision is made for nephron-sparing surgery or for reimplantation of a megaureter in association with ureteral tapering.

Technique

With the patient in a supine position, flexible cystoscopy is performed and a ureteral stent is placed in the ureter if possible. For this reason, the genitalia must always be prepared into the operative field. If retrograde stenting is not possible, a nephrostomy tube may temporarily relieve renal obstruction.

A transperitoneal approach is usually preferred. The pneumoperitoneum is obtained in the standard fashion, and three to four ports are usually used. One 10-mm port for the camera (5 mm for children) is placed just below the umbilicus, while two working ports (10–12 mm or 3 mm) or the two robotic arms (8-mm ports) are positioned in the lower quadrant in the mid-clavicular line and 1 inch below the umbilicus. A fourth trocar (3–5 mm or 12 mm for the robot-assisted procedure) is placed suprapubically or in the contralateral lower quadrant (see Figures 86.8 and 86.13). Alternatively, the three working ports can be placed along an imaginary shallow Pfannenstiel incision; two lateral at the mid-clavicular line and one in the midline. The advantage of this configuration is that it allows for inconspicuous conversion. With the surgeon on the contralateral side, the colon is flexed, and the ureter is identified above the bifurcation of the iliac vessels and dissected caudally. Once the ureter becomes entrapped in scar tissue, it is transected, taking care to excise any nonviable tissue. The healthy ureter is then sharply spatulated posteriorly.

The bladder is filled with 200 mL of normal saline, and the overlying peritoneum is divided between the obliterated umbilical ligaments. This allows entrance into the space of Retzius, and the bladder can then subsequently be further mobilized by dividing anterolateral attachments. When performing a bladder dome advancement technique, no further mobilization is typically necessary. When performing a psoas hitch for longer strictures, the contralateral bladder pedicle may need to be divided before suturing the bladder to the ipsilateral psoas tendon. The ipsilateral anterior bladder wall is then opened transversely (2–3 cm), one-third of the distance from the dome to the bladder neck. A Boari flap procedure can then be performed using the anterior bladder flap created as in open surgery. The middle portion of the posterior flap is then sewn to the apex of the spatulated ureter. Suturing the anastomosis is performed with interrupted or continuous 4-0 polyglactin sutures. Once the posterior anastomosis is completed, a ureteral stent is passed proximally over a guidewire that is placed through an inferior trocar. When the stent cannot be directed into the proximal ureter secondary to a poor angle, it may be passed transurethrally with the flexible cystoscope or percutaneously through a large bore angiocatheter. With the ureteral stent in place, the anterior anastomosis is completed, and the remaining bladder is closed in a longitudinal Heineke–Mikulicz fashion. For a psoas hitch procedure, interrupted polydioxanone sutures are used to approximate the bladder dome to the psoas tendon to allow for a tension-free vesicoureteral anastomosis. Finally, the anastomosis is checked by instilling 300 mL of saline into the bladder, and any additional interrupted sutures are placed as necessary.

If the ureter is going to be reimplanted in an antireflux way, the most commonly described technique has been the laparoscopic Lich–Gregoir reimplantation. When the mobilization has reached the bladder wall, scissors score the bladder serosa for 3 cm in a straight line. The bladder musculature is dissected to the mucosal layer, and the flaps of the trough are developed. The dissection proceeds around the ureter onto the lateral and medial aspects of the UVJ, resulting in an inverted Y configuration. At this point, the bladder mucosa can be seen bulging outwards. The ureter is tucked in the tunnel, and the muscle sutured over it with interrupted 3-0 polyglactin 910 at 0.5-cm intervals. The first suture should not be placed at the very end on the inverted Y in order to avoid kinking of the ureteral orifice. The ratio of tunnel length to ureteral diameter should be 5 : 1 [92]. Assessment of the ureteral position is made with the bladder variably distended. Greatly distending the bladder will further flatten the posterior wall, producing a straight ureteral course along the retroperitoneum.

A Jackson–Pratt drain is placed through the lateral 10-mm trocar site, placed on bulb suction, and removed on the second postoperative day when output is usually minimal. The Foley catheter is removed 7 days after cystography reveals no evidence of extravasation and the ureteral stent is subsequently removed at 4–6 weeks later. Renal function and ureterovesical functional patency is evaluated at 3, 6, and 12 months according to surgeon's preference.

Results

Laparoscopic ureteral reimplantation is feasible and safe. The first case of such a procedure in an adult patient was presented by Reddy and Evans [93]. The primary difference between children and adults is that,

during dissection, in children the ureter is readily identified due to the paucity of retroperitoneal fat.

As laparoscopic urologists have gained experience, more technically challenging approaches to reimplant the ureter have beenreported. Transvesical cross-trigonal Cohen antireflux ureteroneocystostomy has been performed with success [94]. A recent comparison between adults and children undergoing this procedure showed no significant differences for this procedure in the two populations [95]. Several reports of reimplanting a megaureter after tapering or excisional tailoring exist also [96]. Tapering can be performed both intracorporeally and extracorporeally [97].

The largest series of laparoscopic ureteral reimplantation to date by Seidman *et al.* included 45 consecutive patients with a success rate of 96% during a mean follow-up period of 25.2 months [98]. Mean stricture length was 3.0 cm, while 56% of patients had had previous open abdominal surgery. This might explain the significant complication rate of 15.5% seen in this series. Among them were two inadvertent ureterotomies attributed to the difficult dissection often associated with such cases. According to the authors, ureteral viability and adequate tissue vascularity are paramount for success. All reimplantations were performed in a refluxing manner and no problems were associated with this technique.

In a comparative study between laparoscopic and open reimplantation, functional outcomes were comparable, while laparoscopy offered the advantages of minimal invasive surgery, namely less postoperative analgesics, shorter hospital stay (9.2 days vs 19.1 days), and faster convalescence (2.3 weeks vs 4.2 weeks). However, operative time was longer for laparoscopic ureteral reimplantation (228 min vs 187 min) and a high degree of laparoscopic expertise was necessary [99].

Experience with robot-assisted reimplantation is limited. However, it is feasible and safe. Boari flap reimplantation with or without psoas hitch has been reported [100, 101]. Results were excellent with 100% success after a 15.5-month follow-up, while hospital stay, convalescence, EBL, operative time, and analgesic requirements were comparable to those obtained with conventional laparoscopy. Small series of robotically repaired obstructive megaureters with intracorporeal or extracorporeal ureteric tapering and ureteroneocystostomy have been reported with success as well [102]. Similarly, robot-assisted laparoscopic surgery was applied to patients requiring distal ureterectomy and reimplantation for lower third ureteric tumors [103].

Ureteroureterostomy for the retrocaval ureter

This entity is very rare. The diagnosis is made by IVP with the characteristic S-shaped course of the ureter. Both transperitoneal [104, 105] and retroperitoneal [106] approaches have been reported. This procedure has also been performed with robotic assistance [107].

Technique

After a stent is passed, the patient is placed in a modified right lateral flank position, and after abdominal insufflation with the Veress needle, three ports are placed, one in the umbilicus, one midway between the xiphoid and the umbilical port, and one at the lower midline (see Figure 86.5). For a robot-assisted procedure, the 10-mm port for the camera is inserted in the umbilicus, and the two 8-mm ports for the robotic arms are placed with one under the costal margin in the midclavicular line and the other two-thirds of the way between the anterior superior iliac spine and umbilicus (see Figure 86.7). A further 5-mm port is inserted 3 cm below the camera port for the assistant to perform retraction, suction, and suture handling. The robot is then docked.

Further surgical steps are identical between robotic and pure laparoscopy. The peritoneum is incised at the line of Toldt, the colon is flexed medially, and the ureter is identified and separated from the posterior surface of the vena cava. The proximal ureter is often dilated. The ureter is then divided at the most distal segment of the dilated ureter. The distal ureteral stump is dissected anterior to the vena cava and spatulated. The two ends are sutured either free hand or robotically. A drain is placed and the operation is concluded in the standard fashion.

Postoperatively the drain is removed when the output is minimal; oral intake starts on the first postoperative day, and the patient's activities are advanced as tolerated. Follow-up includes an IVP 3, 6, and 12 months postoperatively.

The retroperitoneal approach starts with balloon dissection of the retroperitoneal space through an incision at the tip of the 12th rib. Working ports are placed in a configuration similar to that used during a retroperitoneal pyeloplasty (see Figure 86.10). The rest of the procedure is identical to the transperitoneal approach.

Results

Both the retroperitoneal [108] and the transperitoneal [109] approaches are feasible and safe. Small series of seven and four patients, respectively, have confirmed the advantages of laparoscopy, such as less postoperative pain, shorter hospital stay, and faster recovery, without compromising surgical outcome. No complications were reported. Experience with reconstructive laparoscopic surgery has allowed surgeons to become faster, significantly reducing operating times to a mean of 128.6 min and 210 min for the retro- and trans-

peritoneal approaches, respectively. A case of pure robotic retrocaval ureter repair has been reported but more data are required before conclusions can be made [110].

Ureteroureterostomy/laparoscopic repair of ureteral injury

Closed injury of the ureter is usually iatrogenic, most often occurring during endoscopic manipulation [111] or laparoscopic gynecologic procedures [112]. Small perforations can heal spontaneously with stenting; larger injuries, however, require definitive repair. Laparoscopy, both pure and robot assisted, allow minimally invasive correction of the injury, either by suturing the ureteral tear or by performing an end-to-end ureteroureteral anastomosis [113, 114].

Although short-term follow-up shows good results, only limited postoperative data are available to define stricture recurrence and other complications [115].

Laparoscopic cutaneous ureterostomy

Cutaneous ureterostomies are performed for palliation from advanced malignant disease. Open surgery is quite morbid in these patients. Placement of nephrostomy tubes has considerably decreased the complication rate. Nevertheless, the quality of life is often poor, with tube changes required and problems arising due to obstruction and dislodgement.

Laparoscopic cutaneous ureterostomy has been reported with good results [116]. The technique is more complex than placing a nephrostomy tube, and Puppo *et al.* suggest that this procedure be offered only when life-expectancy is more than 6 months [117].

The technique involves standard laparoscopic dissection of the ureter, which is cut as low as possible. After the ureter is freed in the abdominal cavity, it is grasped with an endo-Babcock and withdrawn through one of the lateral ports after the abdomen is deflated. The cutaneous ureterostomy nipple is then performed in the usual manner extracorporeally.

Robot-assisted ureterostomy has not been reported, but it is likely that it can be used as well with success.

Anastomoses between the bowel and the ureter

Several case reports of laparoscopic formation of an ileal ureter completely intrabdominally have been reported. In a comparative study, seven patients undergoing laparoscopic ileal ureter formation were compared to seven patients undergoing the same but open procedure [118]. Narcotic analgesic use and time to convalescence were significantly less in the laparoscopic group, while a trend toward shorter hospital stay (5 days vs 8 days, $P = .101$) was also noted in patients in the laparoscopic group. There was no evidence of anastomotic stricture for patients in either group. Despite the small number of patients involved, a significant advantage was noted for postoperative recovery after laparoscopic compared to open ileal interposition.

Alternatively the ileal segment can be managed extracorporeally through a McBurney incision or a 3-cm infraumbilical incision [119]. This decreases operative time, which was reported to be a mean of 195 min. This time is much shorter than the 8 h reported in initial cases [120].

Initial experience of performing an ileal ureter with robotic assistance or with single-port laparoscopy has been reported, but experience is limited [121, 122].

During laparoscopic or robot-assisted radical cystectomy, the ureters are implanted in the ileal neobladder or in the ileal conduit. Technical details concerning ureteroileal anastomosis in this setting are presented above in the laparoscopic cystectomy section.

Despite the fact that bowel reconstruction is frequently performed extracorporeally through a small incision, there are many reports of pure and robot-assisted laparoscopic radical cystectomy and urinary diversion preformed totally intracorporeally [123–127]. Both types of ureteroliteal anastomosis, refluxing and nonrefluxing, have been described [128]. Although results concerning ureteroileal anastomosis are not always mentioned and data extraction is difficult, rates of stricture formation and refluxing anastomosis are similar to those seen in open cases during mid-term follow-up. Specific studies evaluating long-term effectiveness of laparoscopically performed ureteroileal anastomosis (conventional and robot assisted) are needed.

Complications

General complications of laparoscopic surgery have been well documented and should always be kept in mind. Complications specific to laparoscopic ureteral reconstruction occur as a result of injury to the ureter and can be minimized by adhering to basic laparoscopic dissection techniques and with experience. Excess traction during dissection can cause ureteral avulsion, especially with robot-assisted surgery due to the lack of tactile feedback. Moreover, prolonged tension in one area can lead to ischemic injury with resultant necrosis, extravasation, and stricture formation. If an anastomosis has been performed, excess manipulation of the ureter can result in disruption of the suture line. At the conclusion of any procedure, the ureter should be carefully inspected to rule out ureteral extravasation.

Vigorous retraction of the ureter can cause proximal or distal migration of an indwelling ureteral stent, resulting in ineffective postoperative drainage. Possible complications from inadequate drainage include

ureteral fistulas, urinoma formation, and severe postoperative abdominal pain. These may be prevented by using a stent of adequate length, such that retraction will allow both ends to remain in proper position. An abdominal radiograph and cystoscopy should be performed after each procedure to document stent position. Closed drainage can be effective postoperatively if leakage occurs. This usually takes place within 48 h of surgery. Management consists of converting the leak into a controlled fistula by maintaining drainage for at least 1 week. Prior to removing the drain it should be taken off suction to be sure output decreases over 24–48 h.

As in open surgery, care should be taken to perform a tension-free repair to avoid increasing the risk of ureteral stricture. A follow up IVP or renal scan after stent removal is recommended to evaluate if there is stricture formation.

CHAPTER 87

Laparoscopic and Robotic Techniques for the Management of Pelvic Organ Prolapse

Courtenay K. Moore & Raymond R. Rackley

Center for Pelvic Health and Reconstructive Surgery, Glickman Urological Institute at Cleveland Clinic, Cleveland, OH, USA

Introduction

Abdominal surgery for pelvic organ prolapse (POP) has a long history, beginning with procedures to secure the uterus to the anterior abdominal wall (Mayo procedure). Eventually, attempts to create a more natural vaginal axis and to prevent enterocele formation led to the suturing of the vaginal apex directly to the anterior longitudinal ligament of the sacrum. The subsequent addition of a piece of material (usually synthetic) between the vaginal apex and the sacrum led to the contemporary version of the abdominal sacrocolpopexy. In patients desiring a uterine-sparing approach, modifications of the abdominal sacrocolpopexy or uterosacral ligament plication procedures have been proposed. While these procedures have documented efficacy and are applicable to a wide variety of patients, their use has been limited due to their invasiveness and prolonged recovery times.

With the advent of laparoscopic techniques in the 1990s, interest in laparoscopic approaches to prolapse repair surged. The laparoscopic approach offers the success, versatility, and durability of the traditional abdominal repairs with a minimally invasive approach and shortened recovery. As technology has continued to advance, robotic and now laparoendoscopic single-site (LESS) surgery have continued to change the management of POP. In this chapter, we review laparoscopic and robotic approaches to the management of POP and mesh complications.

Laparoscopic uterosacral ligament suspension

The use of the uterosacral ligaments for the treatment of vaginal vault prolapse is well-established [1–3]. In the laparoscopic technique described by Lin *et al.*, the patient is placed in the dorsal lithotomy position [4]. After placement of a Foley catheter, a 10-mm laparoscope is inserted through an intraumbilical vertical incision, and four additional 5-mm incisions are made in the lower abdomen. The two lower incisions are lateral to the deep inferior epigastric vessels, while the upper pair are placed lateral to the rectus abdominis muscle at the level of the umbilicus. The patient is then placed in steep Trendelenburg. The next step is the identification and dissection of both ureters from the pelvic brim to the deep pelvis. This is done to prevent ureteral kinking at the time of suture placement or injury during the vaginal vault suspension. An endoanal sizer is placed in the rectum, while two fingers are placed into the vagina to palpate the ischial spines. The exact location of the ischial spines are visualized laparoscopically. Nonabsorbable figure-of-eight suture are then placed through the uterosacral ligaments at the level of the ischial spines, approximately 2 cm medial to the ischial spine and away from the rectum, and brought through the ipsilateral vaginal apex, avoiding entry into the vaginal canal. During suture placement, the rectum is pushed to the contralateral side to avoid injury. This is performed bilaterally and concomitant repairs may then also be performed.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Over the last 10 years, the data on laparascopic uterosacral suspension have consisted mainly of case reports and small cohort series. In a retrospective study of 133 patients, Lin *et al*. reported no recurrence of prolapse in 87.2% patients at a mean postoperative follow-up of 3.2 years [5]. The major complication rate was 2.25%. This study is consistent with other smaller series with a 75–100% cure rate at less than 1 year and a complication rate of 2–9.5%, with the most common complication being ureteric injury [6].

In a study comparing 25 laparoscopic to 25 vaginal uterosacral vault suspensions, the laparoscopic route had lower estimated blood loss (EBL) ($P < .0001$), shorter hospital stay ($P < .002$), and no recurrences versus three recurrences in the vaginal group [6]. This technique has also been used in women with a uterus. The procedure is as described above, however, the uterosacral ligaments are sutured together using one purse-string permanent suture through the uterosacral ligaments close to the sacrum and then through the posterior cervical ring. A second permanent suture plicating the uterosacral ligaments together in the midline, 2 cm posterior to the first suture provides additional reinforcement [4]. Several studies suggest that women with cervical elongation greater than 5 cm are at increased risk for failure, citing sensation of symptomatic vaginal bulge from the elongated cervix extending down the vaginal canal [4].

While the literature on laparoscopic uterosacral ligament suspension contains no large-scale, prospective, comparative trials, the results from the above case series combined with the proven history of uterosacral vault suspension via the vaginal approach suggest that this may be a promising addition to the array of procedures used to address pelvic organ prolapse. It may also have a specific role in patients who wish to preserve the uterus and in patients wishing to avoid the use of synthetic mesh.

Laparoscopic sacrocolpopexy and uterine-sparing laparoscopic sacrouteropexy/colposacropexy

Since its introduction by Nezhat in 1994, laparoscopic sacrocolpopexy has undergone several modifications [7]. In the original report, a single piece of Gortex mesh was attached to the posterior vaginal apex and sutured or stapled to the anterior longitudinal ligaments of the sacrum. Since its inception, modifications to the procedure have been made, including the use of anterior and posterior pieces of polypropylene mesh. The procedure can be modified for patients desirous of preserving the uterus by using a single piece of posterior mesh or an anterior Y-shaped piece of mesh and a posterior mesh.

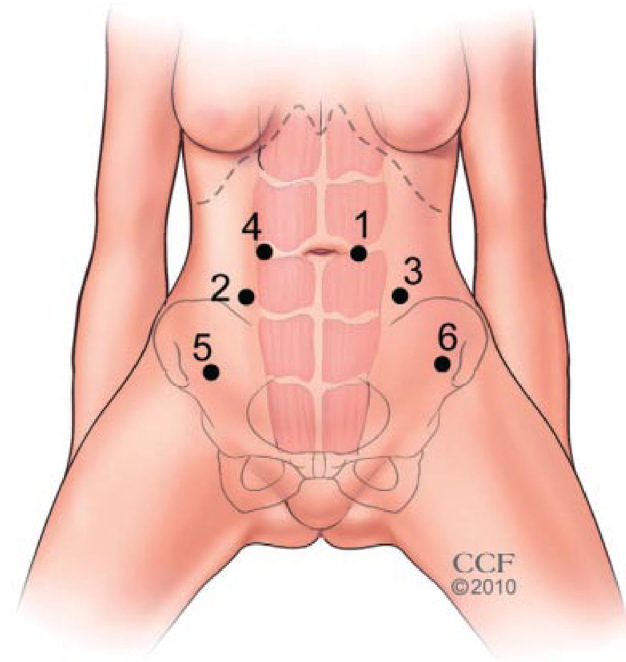

Figure 87.1 Port placements for laparoscopic pelvic organ prolapse surgery. A fifth port (5 mm) may be placed in the left lower quadrant, or a suture may be used to retract the sigmoid colon. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

Most techniques described for laparoscopic sacrocolpopexy involve the same initial steps. With the patient in the dorsal lithotomy position with the arms tucked, four or five ports are placed (Figure 87.1). After obtaining access using either the Hasson open technique or the Verress needle, a 10–12-mm intra- or infra-umbilical port is placed. Two additional 10–12-mm ports are placed lateral to the rectus muscle. One or two additional 5-mm ports are placed 2–3 cm cephalad and 2–3 cm medial to the anterior superior iliac spines, avoiding ilioinguinal and iliohypogatric nerve injury or entrapment. The left lower port is utilized to retract the sigmoid colon to the left and cephalad (Figure 87.2). This port can be eliminated by using a suture to retract the sigmoid. A 1-0 monofilament suture on a large (CT-X) needle can be passed into the left lower quadrant, through an epiploic appendage of the sigmoid colon, and back out through the left lower quadrant, and clamped at the skin level to retract the sigmoid colon.

After the sigmoid is retracted, the sacral promontory, right common iliac artery, and right ureter are identified. The posterior peritoneum over the sacral promontory is incised longitudinally to the level of the vaginal apex. An endoanal sizer is placed in the vagina; thereby reducing the prolapse and elevating the vagina for exposure (Figure 87.3). The peritoneum over the vaginal apex is then incised, and this dissection is continued

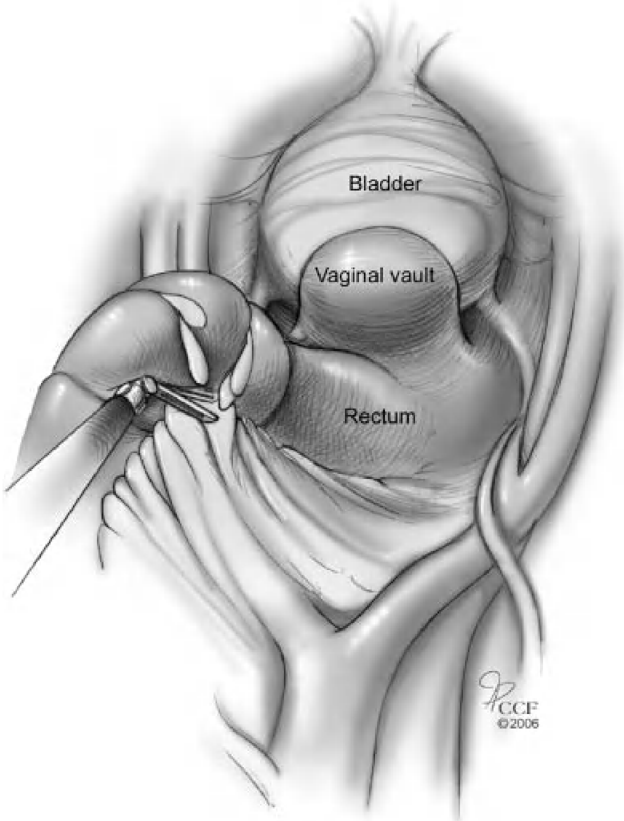

Figure 87.2 Retraction of the small bowel and sigmoid colon allows exposure of the sacral promontory. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

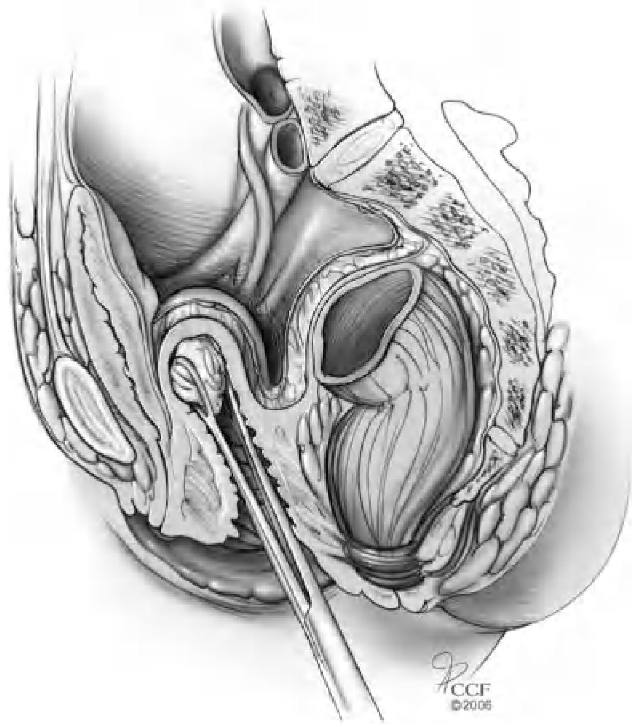

Figure 87.3 Placement of an endoanal sizer in the vagina reduces the prolapse and elevates the vagina for exposure. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

anteriorly along the vaginal wall dissecting the plane between the bladder and vagina (Figure 87.4). The bladder can be filled to help demarcate this plane, or by introducing a cystoscope light into the bladder. This plane is dissected at least 3 cm distal to the vaginal apex to allow space for placement of the anchoring sutures. The lack of direct tactile feedback makes this dissection challenging; resulting in a cystotomy or sutures in the bladder in 10.7% of cases making cystoscopy imperative [8]. Similar dissection is performed on the posterior vaginal wall to deperitonealize this area and separate the vagina from the rectum posteriorly. The mesh, either in two separate strips (3–5 cm x 12–15 cm) or prefashioned in a Y-configuration, is passed into the field and sutured with nonabsorbable suture to the posterior and then the anterior vaginal wall. At least four sutures are required on either side to fully anchor the mesh. With the prolapse reduced via the endoanal sizer, the proximal end of the mesh is anchored to the anterior longitudinal ligament of the sacrum with two or more nonabsorbable sutures (Figure 87.5). The excess mesh is trimmed and the posterior peritoneum is then closed over the mesh (Figure 87.6). Cystoscopy should be performed at the end of the procedure to ensure ureteral patency and that none of the sutures have passed into the bladder.

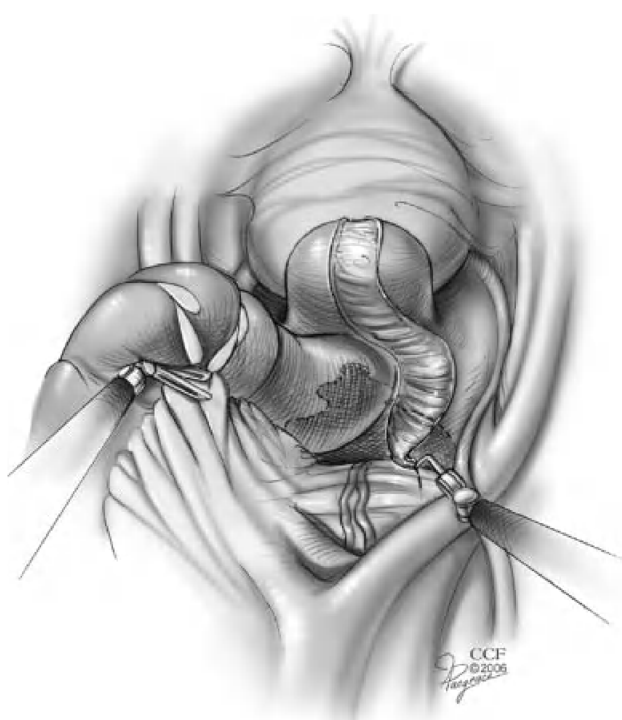

Figure 87.4 Peritoneum over the vagina apex is incised longitudinally to the level of the sacral promontory. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

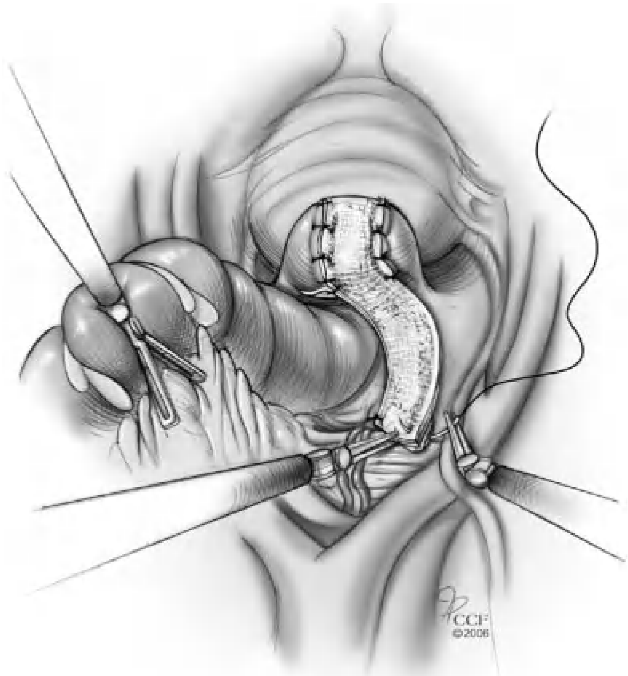

Figure 87.5 Mesh is introduced and sutured to the vaginal apex anteriorly and posteriorly and sutured to the sacral promontory. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

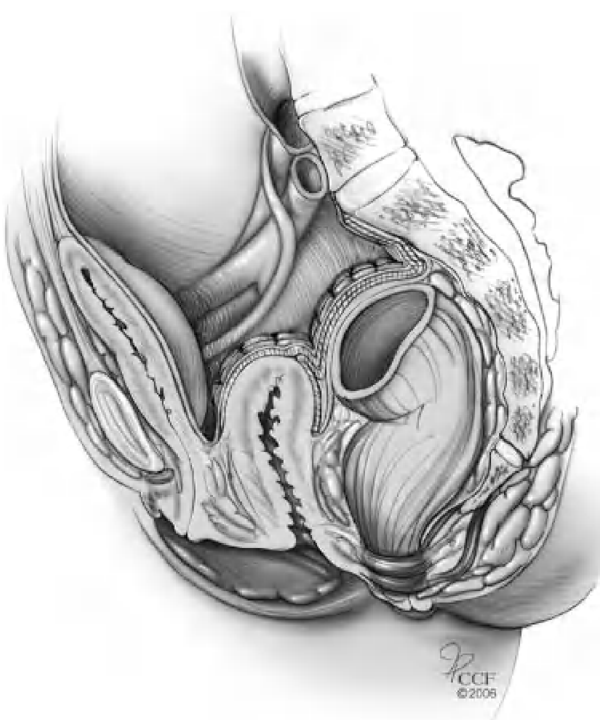

Figure 87.6 Mesh is covered by the posterior peritoneum. The vagina is suspended to the sacral promontory, recreating normal vaginal anatomy. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

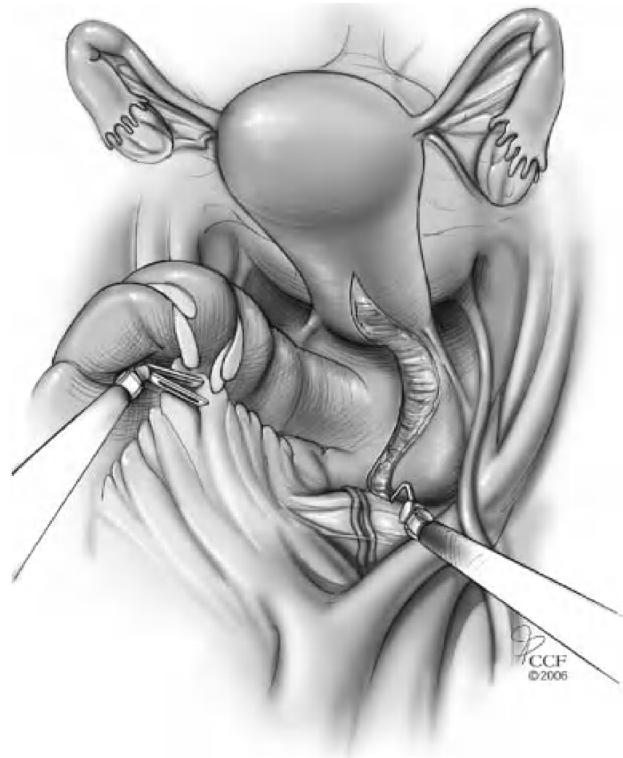

Figure 87.7 In sacrouteropexy, the posterior peritoneum overlying the posterior vaginal cuff and cervix is incised longitudinally to the level of the sacral promontory. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

In patients undergoing sacrouteropexy, the posterior peritoneum is incised from the level of the sacral promontory, caudally to the level of the posterior vaginal cuff and cervix (Figure 87.7). Depending on surgeon preference, a single piece of posterior mesh (3–5 cm x 12–15 cm) or an anterior Y-shaped piece of mesh and a posterior mesh are used. In cases using a single piece of mesh, the mesh is sutured to the posterior vaginal cuff and posterior cervix using 0-nonabsorbale sutures. When using two pieces of mesh, the posterior mesh is placed as described, while each arm of the anterior Y-shaped mesh is passed through the broad ligament. The mesh(es) are fixed to the sacrum as described above.

Laparoscopic sacrocolpopexy appears to successfully recapitulate the open technique that has demonstrated durable results for several decades. Several studies have demonstrated the laparoscopic approach to be successful, with a 90–96% cure rate and a low mesh erosion rate, ranging from 1% to 8%. [10] The largest series of laparoscopic sacrocolpopexies is a retrospective cohort of 165 patients followed for a mean of 43 months. [11] Of the 165 patients, 27 were lost to follow-up. Success rate at mean follow-up was 94.9%, with 5.07% patients reporting recurrent vaginal vault prolapse and 3.62% a recurrent cystocele.

A comparative cohort study from our institution compared 61 patients treated with open sacrocolpopexy and 56 treated laparoscopically with a mean follow-up of 16 and 14 months, respectively. The mean total operative time was longer for the laparoscopic group (269 min vs 218 min), but hospital stay was shorter in the laparoscopic group (1.8 days vs 4.0 days) [8]. Reoperation rates (11% laparoscopic vs 5% open) and clinical outcomes rates were similar. The sample size was not powered adequately to detect differences in complication rates.

Robotic laparoscopic sacrocolpopexy and sacrouteropexy

This modification of the laparoscopic sacrocolpopexy utilizes the robotic system to facilitate three-dimensional visualization of the operative field, placement of sutures, and tying of the sutures; thereby simplifying the execution of maneuvers and shortening the laparoscopic learning curve. Five ports are typically utilized: an umbilical (intra-, infra- or supra-umbilical) 12-mm camera port; two 8-mm robotic ports placed at the lateral edge of the rectus abdominal muscles (8–10 cm lateral to the camera port) at the level of the umbilicus or 1–2 cm caudal; and traditionally two additional ports, a 5- and a 10-mm or two 10-mm ports, are placed bilaterally 3 cm medial and cephalad to the anterior superior iliac spine to allow an assistant to retract the sigmoid colon and small bowel (see Figure 87.1). At least one of these ports should be 10 mm to allow passage of the mesh strips and needles as needed. In women with small pelvises, we place the accessory 10-mm port 8 cm lateral and 2–3 cm cephalad to the umbilical port. Once access is obtained and the robotic arms positioned, the technique is identical to that described for laparoscopic sacrocolpopexy (see Video 87.1). The robot can be docked between the legs or side docked. As in the laparoscopic procedure, the uterus can be spared by performing a robotic sacrouteropexy as described above.

Several studies have demonstrated the feasibility of this procedure with excellent short-term results. Ayav *et al*., in a series of 18 patients at 6-month follow-up, reported that none had recurrent prolapse in any compartment [12]. Similarly, Dimarco *et al*. followed five women for a mean follow-up of 4 months with no recurrent anterior, posterior, or apical prolapses [13]. Elliot *et al*. followed 21 patients for 1 year and reported a 95% apical cure rate and a 100% subjective surgical satisfaction rate [13]. Two more recent larger series by Akl *et al.* and Shariati *et al*., who followed 80 and 77 patients undergoing robotic sacrocolpopexy, respectively reported recurrent prolapse in 3.7% and 1.29% of patients, respectively [14]. Intra- and post-operative complications rates are low. In the largest study to date, Akl *et al*. reported a 1.2% cystotomy rate, 1.2% ureteric injury rate, 1.2% enterotomy rate, 1.2% postoperatve ileus rate, and 6% mesh erosion rate [14].

In a retrospective study comparing 73 robot-assisted sacrocolpopexies with 10 open abdominal sacrocolpopexies 6 weeks postoperatively, Geller *et al*. found the robotic group to have slightly better POP-Q "C" points, –9 compared with –8 ($P = .008$) [15]. All other anatomic outcomes were similar. Robotic procedures had statistically less blood loss (103 ± 96 mL vs 255 ± 155 mL, $P < .001$), longer total operative time (328 ± 55 min vs 225 ± 61 min, $P < .001$), shorter length of stay (1.3 ± 0.8 days vs 2.7 ± 1.4 days, $P < .001$), and a higher incidence of postoperative fever (4.1% vs 0.0%, $P = .04$) [15]. At the 31st Annual American Urogynecological Society Meeting, Paraiso et al. presented an abstract on the on the first randomized controlled trial comparing robotic to laparscopic sacrocolpopexy. The initial findings at 1 year showed similar anatomical and functional outcomes with the robotic sacrcolopexy being more expensive, and requiring longer operating times. [9].

Laparoscopic-assisted percutaneous vaginal tape vault suspension and uterine suspension procedures

Besides the obvious benefits in recovery time and incision size, one of the benefits of laparoscopy in pelvic surgery is the ability to visualize internal anatomy while working on an external structure. This principle was utilized in creating the laparoscopic-assisted percutaneous vaginal tape vault suspension (Lap PVT-VS; Figure 87.8) and subsequently, the uterine suspension procedure, Lap PVT-US; Figure 87.9) at the Cleveland Clinic (see Video 87.2). In these novel procedures, the surgeon, operating vaginally, passes a strip of synthetic mesh percutaneously under the lateral walls of the vagina using angled trocar needles, while monitoring the needle's passage both with vaginal inspection and laparoscopic visualization. In order to avoid bladder and bowel injury, as well as to allow use of the technique in a uterine-sparing fashion, the mesh strips are passed along the lateral walls of the vagina. This allows the mesh to provide support along the full length of the vagina, rather than just supporting the apex as in other sacrocolpopexy procedures; consequently, fewer concomitant transvaginal procedures (perineal body repairs, rectocele repairs) are required [8].

The initial steps of this procedure are identical to the laparoscopic sacrocolpopexy. After the peritoneum over the sacral promontory and down toward the vaginal apex has been incised, the prolapse is reduced with a bivalve speculum. Two small stab incisions are made in the labial folds just lateral to the vagina at the 4 and 8 o'clock positions near the perineal body (Figure 87.8). Strips of polypropylene mesh, cut 20 cm long and 15 mm wide, are passed using trocar needles with a suture tied

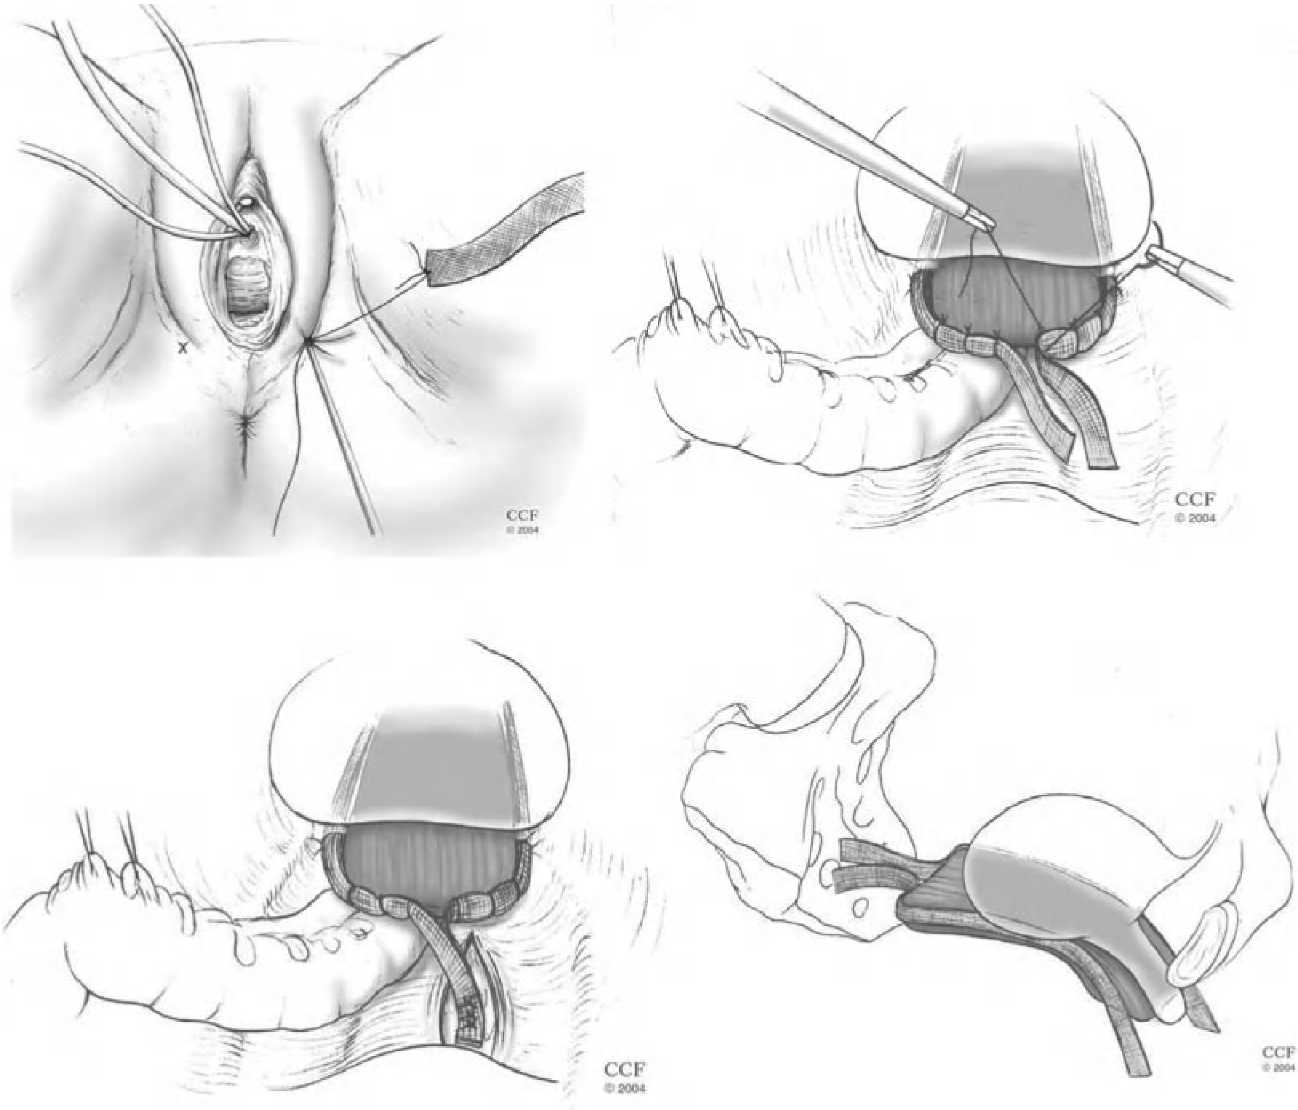

Figure 87.8 Laparoscopic percutaneous vaginal vault suspension procedure. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

to the mesh. Care is taken to pass these in the plane below the full thickness of the vaginal wall; inadvertent button-holing of the vaginal wall may easily be managed by pulling back and redirecting the needle. The laparoscopic view is used to help direct the mesh toward the area just lateral to the vaginal apex, where the trocar needles are passed into the abdomen. The mesh is then grasped laparoscopically and pulled into the laparoscopic field. The mesh strips are left along the entire length of the vagina, and trimmed at the level of the labial skin. Each mesh strip then requires only one stitch to hold it in place, as local tissue reaction to the mesh will fix it in place within 2 weeks, similar to sling fixations for urethral support procedures (Figure 87.8). A third stitch is thrown near the apex, joining both mesh strips to each other and to the vaginal muscularis. With the prolapse reduced, the proximal end of the mesh is fixed to the anterior longitudinal ligament of the sacrum as in the traditional approach. Figure 87.8 shows the proper placement of the mesh along the lateral vaginal walls, noting the relation to the cervix in a uterine-sparing case.

To date we have performed this procedure on 58 patients; analysis of the first 32 cases with a mean follow-up of 10 months revealed a mean total operating room time of 234 min. Concomitant repairs were infrequent, with seven patients undergoing transvaginal posterior colporrhaphy or perineorrhaphy. No bowel or bladder injuries were noted; complications consisted of a deep vein thrombosis in one patient and a port site hernia in another; two patients (6.25%) required a transvaginal anterior colporrhaphy for recurrent anterior wall prolapse [8]. We are currently collecting long-term follow-up data, including POP-Q scores and sexual function questionnaires. The initial results are very promising for this being a minimally invasive, safe, and

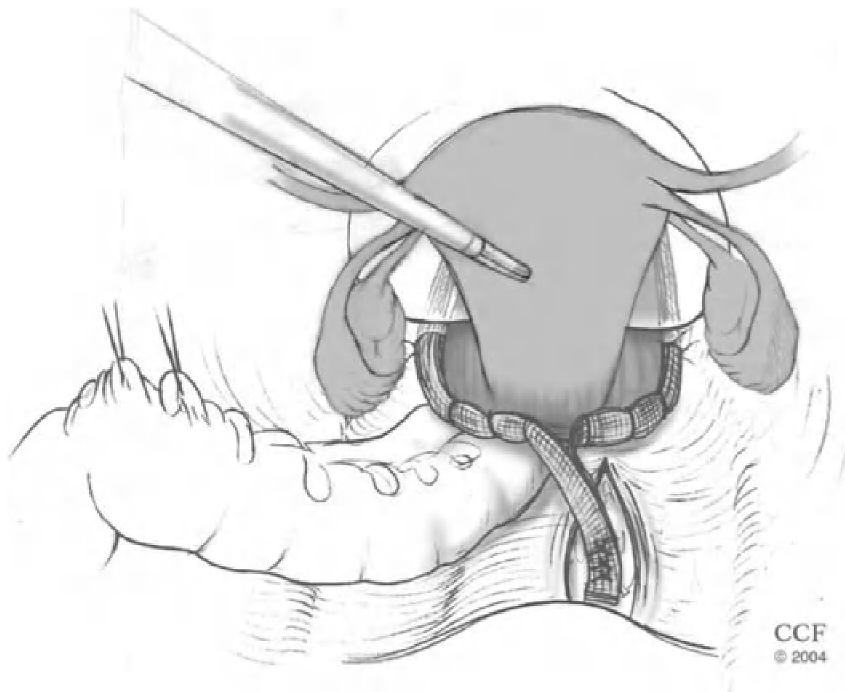

Figure 87.9 Laparoscopic percutaneous vaginal uterine suspension procedure. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

easily learned technique with post-hysterectomy and uterine-sparing applications.

Laparoendoscopic single-site sacrocolpopexy

With improved technology and surgeon experience, laparoscopic surgery through a single incision has become possible. LESS has been used for oncologic renal, prostate, and reconstructive surgery. Pelvic organ prolapse surgery has been added to this growing list of applications.

With the patient in the dorsal lithotomy position with the arms tucked, a 1.5-cm semi-circular incision is made at the inner edge of the umbilicus. Using the Hassan technique, the rectus fascia is incised and four 0-Vicryl fascial sutures are placed to fix the port in place and prevent subcutaneous emphysema. The multichannel port is placed in the incision and secured using the fascial sutures. A 5-mm flexible laparoscope is placed in the camera port. The laparoscopic procedure is performed using the same technique as described previously.

At our institution, 11 cases were performed and nine patients (82%) consented to participate in the study. The mean patient age was 61.6 years (range 39–75 years) with follow-up from 1.3 to –11.7 months. Four (44%) had a uterine-sparing procedure and five (56%) underwent a concomitant sling or cystocele repair. All had at least stage II pelvic organ prolapse. The mean operating time and estimated blood loss were 187 min and 61 mL, respectively. Average length of stay was only 1.4 days, and most patients (78%) had a visual analog pain score of 0 at discharge. Complications included one intraoperative bladder perforation and one wound infection. Two patients required additional surgeries postoperatively. The first patient underwent a cystocele repair and sling at 6 months and the second required a sling at 5 months. Of the four patients who underwent a uterine-sparing procedure, one developed symptomatic uterine prolapse at 9-month follow-up.

Conclusions

Over the last decade new minimally invasive laparoscopic, robotic, and LESS techniques have evolved for the correction of pelvic organ prolapse. All of these techniques aim to achieve the same durable success of the traditional open abdominal techniques, while minimizing recovery, pain, blood loss, and hospital stays. The limited, available data suggest that laparoscopic and robotic outcomes are comparable to those for the open approach in the short term.

CHAPTER 88

Laparoscopic and Robotic Techniques for Repair of Female Genitourinary Fistulas

Lalgudi N. Dorairajan[1] & Ashok K. Hemal[2]

[1]Jawaharlal Institute of Postgraduate Medical Education and Research, Dhanvantari Nagar, Puducherry, India

[2]Department of Urology, Wake Forest University Baptist Medical Center, Winston-Salem, NC, USA

Introduction

Vesicovaginal fistulas usually arise as a complication of gynecologic surgery, especially abdominal or vaginal hysterectomy. Surgeries done for malignant ovarian tumors increase the risk of intraoperative injury to the bladder. Adhesions due to previous infections, endometriosis, and radiotherapy, and infiltration due to malignancy also increase the risk of injury to the urinary bladder as well as the ureter during pelvic surgeries. Other causes of vesicovaginal fistula include radiation for treating pelvic malignancies or as a result of advanced gynecologic malignancies. Vesicovaginal fistulas arising from obstetric accidents, usually obstructed labor or instrumental vaginal delivery, have become rare in the developed world. However, in many less developed countries in the world obstetric fistula is the most common type of vesicovaginal fistula.

In neglected obstructed labor the trigone of the urinary bladder and the bladder neck get wedged between the impacted head and the pubic symphysis. With prolonged ischemia the posterior bladder tissues and the vaginal tissues undergo necrosis, resulting in a vesicovaginal fistula 5–7 days later. They are often large and complex and may involve the bladder neck and upper urethra, thereby threatening the continence mechanism. Sometimes the ureteral orifice may be involved in the scarring, resulting in obstruction and hydroureteronephrosis or a combined vesicovaginal and ureterovaginal fistula. Caesarean hysterectomies done for obstructed labor and rupture of the uterus involving the bladder is the other obstetric situation causing vesicovaginal fistulas. These are caused by ischemic insult as well as direct surgical injury or contusion. Surgical injury to the bladder can also be sustained during difficult caesarean sections, like repeat caesarean sections where the urinary bladder is pulled up by adhesions due to the previous surgery. The resulting fistulas are usually higher up, involving the upper vagina and sometimes the cervix. A bladder injury during caesarean section is the most important cause of a vesicouterine fistula. Improvement in obstetric care is the mainstay in their prevention.

Posthysterectomy vesicovaginal fistula is always the result of an intraoperative injury to the urinary bladder. This may be as trivial as a stitch going inadvertently through the urinary bladder during closure of the vaginal vault. A ureterovaginal fistula may accompany a vesicovaginal fistula or may occur in isolation, and is invariably due to an intraoperative injury to the distal ureter sustained during the pelvic surgery.

Psychologic impact

Whatever the etiology, vesicovaginal fistula has a devastating impact on the social life, sexual function, and self-esteem of the affected woman. The continued contact of urine with the vulva from diapers used to contain the same causes excoriation of the skin and vulvitis. This adds to the ill health of the patient. In the economically poorer countries where most of these fistulas arise from lack of appropriate obstetric care, the patient often cannot afford even diapers. The constant dribble of urine emanates bad odor and the patient becomes a social outcast. The added agony of fetal loss

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

is yet another cause for psychologic upset. Some patients are divorced by their husbands due to their inability to have a healthy sexual relationship. A few patients may actually suffer from depression. Many patients develop amenorrhea due to hypothalamic influence. In a recent study conducted in Nigeria, the incidence of the commonest medical problems present in women with obstetric fistulas were dermatitis (20%), foul smell of urine (15%), recurrent UTI (10%), infertility (5%), amenorrhea (5%), in that order [1]. Socially, 45% of the women interviewed felt ostracized and 50% were economically impoverished by job loss consequent to their developing the fistula. The divorce rate reported in this study was 25%. Therefore, psychologic support and sometimes pharmacotherapy become necessary before embarking on definitive surgery.

Preoperative evaluation

The patient typically presents with incontinence of urine that usually follows delivery or pelvic surgery. Some patients may have an antecedent history of radiation or gynecologic cancer. Usually the patient reports leakage of urine immediately after removal of the catheter following the surgery or obstetric event, but the leakage can start after several days or even a few weeks later. Sometimes, especially in the presence of an isolated ureterovaginal fistula or a small high vesicovaginal fistula, the patient may have a normal voiding pattern in addition to continuous incontinence. Digital vaginal examination helps to identify the fistula and to rule out coexisting pathologies in the pelvis. It also helps assess the accessibility of the fistula for reconstruction through the vagina, extent of fibrosis and associated scarring, and quality of vaginal tissue. A per speculum vaginal examination is needed to accurately identify the presence, number, and location of the fistula. A computed tomography (CT) cystogram demonstrating contrast in the vagina can confirm the presence of a small fistula, that may even have been missed on examination. The three-tampon test described by Moir helps distinguish a vesicovaginal fistula from a ureterovaginal fistula [2]. Cystoscopy is mandatory in every case to assess the number of fistulas, and their size, location, and relationship to the ureteral orifices and bladder neck. It also helps assess the bladder capacity, detect any calculus or foreign body such as suture material, and the presence of any inflammation of the bladder mucosa. A biopsy of the fistula may be essential in cases treated earlier for gynecologic malignancies to rule out presence of cancer. Upper tract function and anatomy is best assessed by CT urography. Twelve percent of vesicovaginal fistulas may be associated with ureteral abnormalities [3]. In case of suspected ureterovaginal fistula or a distal ureteral stricture on imaging, a retrograde ureteropyelogram may be performed just prior to reconstructive surgery for better delineation of the distal ureteral anatomy.

A urine sample for culture must be obtained using a catheter inserted through the urethra or a sterile speculum inserted in the vagina. Any active infection must be treated with appropriate antibiotics. Any indwelling catheter must be removed and tissue edema should be allowed to subside completely, especially in fistulas occurring after delivery. Improving the general condition and nutrition of the patient, correcting anemia, and treating vulval excoriations are important aspects for good healing after surgery. In patients in a hypoestrogenic state, topical application of estrogen creams for a few weeks may improve the quality of vaginal tissues.

Classification of vesicovaginal fistulas

Vesicovaginal fistulas can be classified as simple or complex. The following fistulas are considered as complex:

- Large fistulas;
- Fistulas involving the ureteric orifice, bladder neck or urethra;
- Previous failed repairs;
- Postradiotherapy fistulas;
- Underlying malignancy or granulomatous infections.

Based on their anatomic location, fistulas can also be classified as trigonal or supratrigonal, as seen on cystoscopy, and juxtacervical, high vaginal or mid-vaginal based on the anatomic location on the anterior vaginal wall.

Treatment options for vesicovaginal fistula repair

A period of conservative management by prolonged catheterization for 4–6 weeks may be attempted in fistulas following hysterectomy, but only small fistulas are likely to heal. A decision to start conservative management must be weighed against the good results of early repair, especially in posthysterectomy fistulas. Minimally invasive methods like fulguration of the fistula tract are successful only in a small proportion of cases with small fistulas. There are a few anecdotal reports indicating successful use of biologic sealants like fibrin glue and cyanoacrylic glue for small vesicovaginal fistulas less than 1 cm [4, 5]. The standard treatment remains surgical correction of the fistula.

A period of conservative management of a vesicouterine fistula is justified. Medical management of these fistulas has been attempted with long-acting gonadotrophin-releasing hormone analogs to induce reversible menopause with some success [6, 7]. However,

most cases require surgical repair of the fistula. A few ureterovaginal (or ureterouterine) fistulas with a patent distal ureter may be amenable to endourologic management by endoscopic ureteral stenting [8]. Most ureterovaginal fistulas following pelvic surgery are, however, associated with distal ureteral stricture and are best managed surgically as soon as they are detected. In the presence of active infection and sepsis, a period of antibiotic therapy and urinary diversion in the form of a percutaneous nephrostomy on the affected side may be essential to control infection before contemplating definitive reconstruction.

Timing of surgery for vesicovaginal fistula

Traditionally, a waiting period of 3 months or more after the antecedent event has been followed before embarking on fistula repair. However, this has been recently questioned. The advantages of early repair are obvious and include shortening of the duration of morbidity and psychosocial stress caused by urinary incontinence, and reduction in the cost of managing incontinence. While there is now general consensus that if the fistula is detected within 72 h after gynecologic surgery early repair is indicated, there is often a delay of several days for the diagnosis of the vesicovaginal fistula and its further evaluation. Several reports have shown that fistula repair can be performed within 6 weeks with safety and efficacy [9, 10]. Nagaraj *et al*. have shown that even early laparoscopic repair of a posthysterectomy fistula can be done safely and efficaciously [11]. While we consider that early repair in gynecologic fistulas is justified, there is a lack of uniform consensus regarding the timing of repair.

In the case of obstetric fistulas, we consider it is prudent to wait for at least 6 weeks before performing the repair. This may be justified because the extent of trauma to the bladder and the vagina is difficult to assess at the time of the event. Furthermore, during puerperium there is a phase of negative nitrogen balance that is a part of the normal involution of the pelvic viscera. Nevertheless, it may be noted that a large series from Nigeria has reported a high success rate with early repair even in obstetric fistulas [12].

Principles of repair

The principles of vesicovaginal fistula repair have largely remained unchanged over decades. These include adequate exposure, adequate separation of bladder and vagina, trimming of any devascularized edges of the bladder and vagina, tension-free closure of the bladder and vagina with nonoverlapping suture lines, interposition of vascularized tissue (omentum, peritoneum or Martius flap), and adequate postoperative bladder drainage. In case the ureteral orifice is involved or in the presence of a coexistent ureterovaginal fistula or stricture, ureteral reimplantation is required. Attention must also be paid to the continence mechanism when the fistula involves the urethra or bladder neck or where the bladder capacity is compromised. With the high success rate associated with surgical repairs, attention must also be given to maintaining the vaginal luminal size during reconstruction to retain sexual function [13]. Continence procedures, like a pubovaginal sling in cases of extensive urethral involvement, augmentation cystoplasty for a small bladder, or vaginoplasty for vaginal stenosis, may be required in select cases.

Surgical approaches to repair and indications for an abdominal approach

Surgical repair of a vesicovaginal fistula can be performed through the vaginal or abdominal routes. The absolute indications for an abdominal approach are when the vesicovaginal fistula is associated with:

- Involvement of the ureteral orifice by the fistula;
- A small capacity bladder requiring augmentation;
- Vaginal stenosis from postsurgical scarring or previous radiation;
- Involvement of the cervix or uterus;
- Coexistent ureterovaginal fistula or ureteral stricture requiring ureteral reimplantation.

Vesicouterine or vesicocervical fistulas can only be repaired through the abdominal route. A large supratrigonal vesicovaginal fistula or a previously failed vaginal repair are relative indications for abdominal repair.

Most general urologists prefer the abdominal approach as they are more familiar with the pelvic anatomy, whereas urogynecologists prefer the vaginal approach. The advantages of the vaginal approach include less postoperative pain, less postoperative ileus, avoidance of the complications of a laparotomy, and better cosmesis.

Recently, laparoscopic and robot-assisted laparoscopic methods have been used to decrease the morbidity of an abdominal repair of a vesicovaginal fistula. These techniques have the advantages of reducing the morbidity of surgery by reducing postoperative pain, early resumption of feeding, early ambulation, shorter hospital stay, and better cosmesis as compared to open surgery. These techniques are challenging and there exists a steep learning curve, especially for the purely laparoscopic technique. Robotic assistance using the da Vinci surgical system (Intuitive Surgical, Sunnyvale, CA, USA) has the advantages of depth perception due

to a three-dimensional view, magnification, motion scaling, tremor filtration, and improved dexterity due to the EndoWrist™ technology at the end of the robotic working instruments, permitting movement with seven degrees of freedom. Robotic assistance thus greatly facilitates laparoscopic repair of vesicovaginal fistula.

Indications for laparoscopic or robot-assisted laparoscopic repair of a vesicovaginal fistula

Any patient with a vesicovaginal fistula in whom an abdominal approach to repair is planned is potentially a candidate for undergoing laparoscopic repair of the vesicovaginal fistula. Patients must not have comorbidities that contraindicate laparoscopic procedures, like severe pulmonary or cardiovascular disease or uncontrolled bleeding diathesis. Prior abdominal surgery or a previously failed repair is not a contraindication. Indeed, in most patients the cause of the fistula will have been a previous hysterectomy. Multiple extensive prior abdominal surgeries or previous peritonitis that results in extensive bowel adhesions, and morbid obesity are relative contraindications. A previous history of pelvic radiation is also a relative contraindication at present, as successful laparoscopic repair of a postradiation vesicovaginal fistula has not been reported so far.

Informed consent

The patient must be informed about the different options of surgical repair available and their relative advantages and disadvantages. As in the case for any laparoscopic procedure, the possibility of conversion to an open procedure must be explained to the patient. The possibility of blood transfusion, infection, and injury to adjacent viscera should be explained, as well as the possibility of failure of fistula repair needing reoperation, irrespective of the technique of repair used. In addition, in the case of vesicouterine fistula, the possible need for hysterectomy must be discussed.

Preoperative preparation

Patients using oral anticoagulants like warfarin and Aspirin or other antiplatelet drugs must discontinue these 1 week prior to surgery. Patients are advised to take a clear liquid diet 1 day prior to surgery. All patients undergo mechanical bowel preparation 1 day prior to surgery using polyethylene glycol with electrolyte solution (Golytely™; Braintree Laboratories Inc, Braintree, MA, USA) or a bottle of magnesium citrate (15 g), and a cleansing enema on the morning of surgery. One dose of prophylactic antibiotics (a third-generation cephalosporin and clindamycin) is administered 30 min prior to surgery.

Operating technique of robot-assisted laparoscopic repair of a vesicovaginal fistula

The procedure is performed under general anesthesia. The da Vinci® S robot surgical system (Intuitive Surgical) is the system currently used for robot-assisted laparoscopic procedures. The patient is placed in the lithotomy position. Leg sleeves of an external intermittent pneumatic leg compression device are fixed on the legs to prevent deep vein thrombosis. The patient is prepped and draped, and a digital vaginal examination is performed under anesthesia, followed by a per speculum examination of the vagina using a Sim's speculum and anterior vaginal wall retractor. Urethrocystoscopy is then performed to study the number, location, and size of the fistula, and its proximity to the ureteral orifices and bladder neck. Double- pigtail ureteral stents or 6 F ureteral catheters are passed through the ureteral orifices bilaterally. A Foley catheter of a suitable size based on the size of the fistula is inserted from the vagina into the urinary bladder through the fistula and the balloon is inflated to plug the leak and allow bladder distention during cystoscopy. This catheter is clamped subsequently to prevent loss of pneumoperitoneum when the bladder is opened later during the surgery.

After cystoscopy, the patient is positioned in a steep (60°) Trendelenburg tilt. Pneumoperitoneum can be created using the Veress needle technique or by the open technique (Hasson's technique [14]). For the former, we prefer to insert the Veress needle at the left hypochondrium to avoid adhesions, which are often present due to previous abdominal surgeries. In cases with previous multiple intra-abdominal surgeries or with previous intra-abdominal infections, where the presence of extensive adhesions may make the insertion of the Veress needle potentially dangerous, we use the open technique for establishing pneumoperitoneum. Following creation of pneumoperitoneum, the ports are inserted as shown in Figure 88.1. A five-port transperitoneal approach is used. A 12-mm optical trocar is inserted under endoscopic vision at the umbilicus for the camera. Two 8-mm robotic ports are then placed on either side at the pararectus location over the spinal—umbilical line. Another 8-mm robotic port for the fourth arm is placed on the left side about 5 cm lateral to the left robotic 8-mm port and at least 5 cm above the iliac crest. A 5-mm port is placed on the right side 1 inch above and medial to the anterior superior iliac spine for assistance. We prefer transferring the suture through the robotic or camera port after removing the instrument,

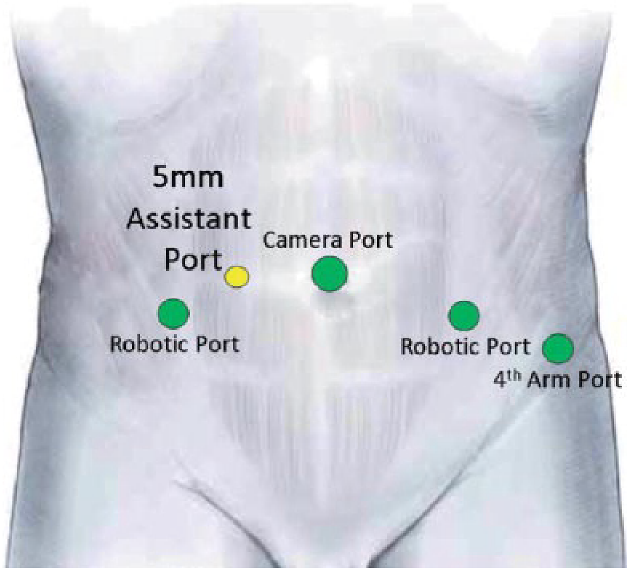

Figure 88.1 Position of ports for robot-assisted laparoscopic repair of a vesicovaginal fistula. In the case of pure laparoscopic repair, the 8-mm robotic ports are replaced with 5-mm ports.

thereby avoiding the need for another 12-mm port. The steps of the surgery are described below.

Step 1: Laparoscopic or robotic adhesiolysis

Laparoscopic adhesiolysis may be required even before the robot is docked to release the adhesions located on the anterior abdominal wall at sites where the ports are proposed to be placed. The robot is bought in from between the legs and docked with the camera and robotic ports. Adhesions encountered are carefully dissected using robotic monopolar curved scissors and Maryland bipolar forceps to expose the superior aspect of the bladder, the uterus if present, and the rectovaginal pouch. The patient-side assistant helps with the suction–irrigator and blunt-tipped grasper. In posthysterectomy cases, the small bowel loops or the sigmoid colon may be adherent to the bladder and vaginal vault, and they must be carefully dissected off the underlying bladder.

Step 2: Cystotomy

A gentle tug on the Foley catheter passing through the fistula further helps locate the approximate site of the fistula as seen from within the abdominal cavity, allowing the creation of a minimal cystotomy in the midline above the adherent area. A midline cystotomy is made using a robotic monopolar curved scissors on the posterior wall of the bladder and it is extended up to the fistulous opening, which is easily identified by the presence of the Foley catheter (Figure 88.2A). The Foley catheter is removed and if the pneumoperitoneum is leaking, then the vagina is packed with a wet sponge to prevent loss of pneumoperitoneum. The cystotomy incision is then extended around the fistula in an inverted racquet fashion. Alternatively, the Foley catheter can be pulled intra-abdominally through the cystotomy by holding its tip with a robotic ProGrasp forceps and used to retract the anterior bladder wall, splinting open the cystotomy to allow better visualization of the fistula and the stented or catheterized ureteral orifices (Figure 88.3). In the case of a vesicouterine fistula, there is no need to pack the vagina as there is no loss of pneumoperitoneum. Furthermore, no catheter is preplaced in the fistula as this is neither feasible nor required.

Step 3: Separation of the bladder and vagina

The bladder is then mobilized off the anterior aspect of the lower uterine segment or vagina. The preplaced stents or ureteral catheters provide an anatomic bearing of the ureteral orifices and help prevent or identify inadvertent injury to the ureters. The fistula is circumscribed, disconnecting the bladder from the anterior vaginal wall. It is not necessary to excise a wide rim of tissue along the edges of the fistula; trimming the edges until well-vascularized tissue is seen is good enough. The plane between the bladder and the vagina is then developed with sharp dissection for a distance of about 2 cm from the fistula to allow tension-free closure on either side. The key point in technique is slow and careful sharp dissection of the fistulous edges, because the trigone and ureteral orifices invariably lie in close proximity. Also, careful dissection helps preserve the vascularity of the tissues and thereby avoids the need for wide excision, which may hamper subsequent closure. The fistulous edges are freshened and bleeding is controlled with bipolar diathermy.

Step 4: Reconstruction of the vagina and bladder, and tissue interposition

The vagina is first closed with a continuous running stitch with 3-0 poliglecaprone (Monocryl) on a round body needle using two robotic large needle drivers (Figure 88.2B). The adequacy of closure is indirectly tested by the lack of loss of pneumoperitoneum upon removal of the vaginal pack. The bladder is reconstructed in two layers using 3-0 poliglecaprone (Monocryl) in a transverse or vertical fashion, based on the defect created after excision or refreshing of the fistulous edges and mobilization of the bladder flaps (Figure 88.2C). However, it is not always possible to perform repair in this manner, especially if the fistula is close to a ureteral orifice. In such cases, we perform a Z plasty modification with the final suture line appearing

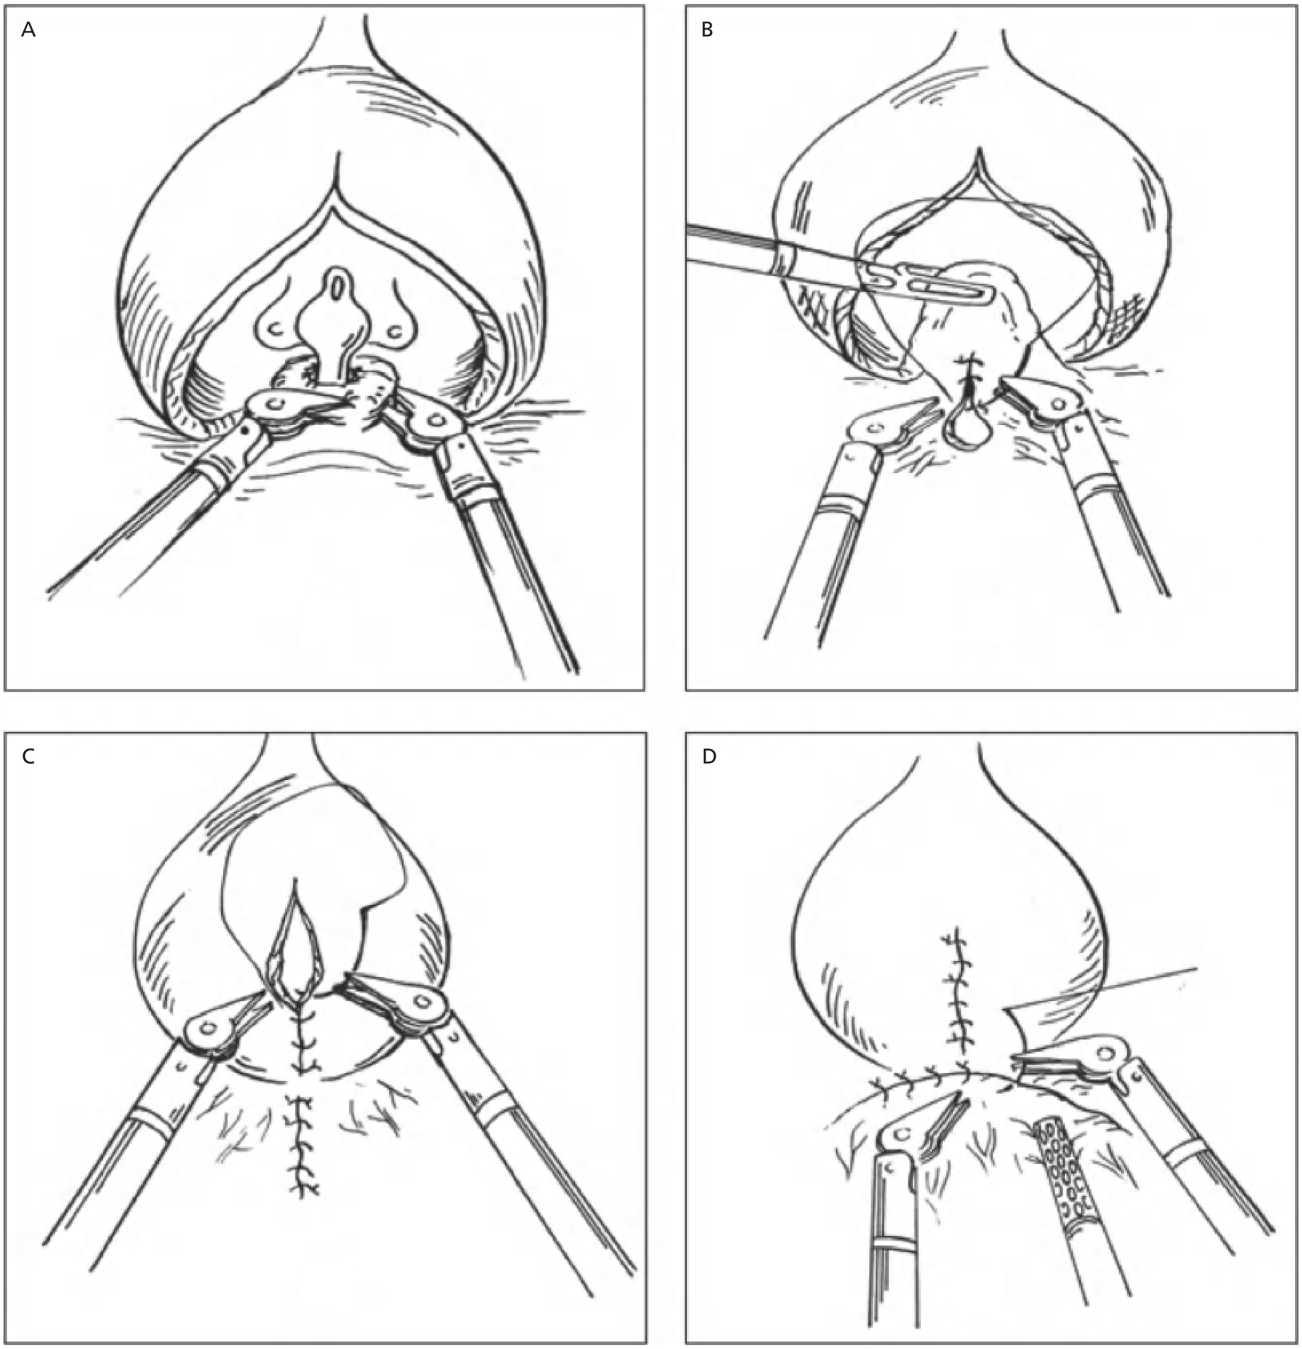

Figure 88.2 Key steps in the repair of a vesicovaginal fistula: (A) Cystotomy and dissection of the fistula using robotic monopolar curved scissors and robotic Maryland bipolar forceps. (B) Reconstruction of the vagina with 3-0 poliglecaprone on a round bodied needle. (C) Reconstruction of the urinary bladder with 3-0 poliglecaprone on a round bodied needle. (D) Interposition of omentum between the urinary bladder and vagina. All intracorporeal suturing is performed using two robotic large needle drivers.

like a Z or an inverted Y, or with a dog-ear on one side. We prefer to interrupt this running stitch by intermittently locking or knotting it to prevent any laxity of the suture line. After final closure, the bladder is moderately distended to assess the integrity of closure with sterile water or saline, which is instilled through an indwelling 18F Foley catheter inserted per urethra. Any minor leakage detected is closed with additional interrupted 3-0 polyglactin (Vicryl) sutures. A well-vascularized pedicled greater omentum is then mobilized and is interposed between the bladder and vaginal suture lines. The omentum is tacked using 3-0 poliglecaprone

(Monocryl) to the resilient vaginal wall, which provides stability, to cover the vaginal suture line (Figure 88.2D). When omentum is unavailable or it cannot be adequately mobilized, the epiploic appendices of the sigmoid colon or a peritoneal flap is used for interposition between the suture lines. A drain is then placed in the rectovaginal pouch.

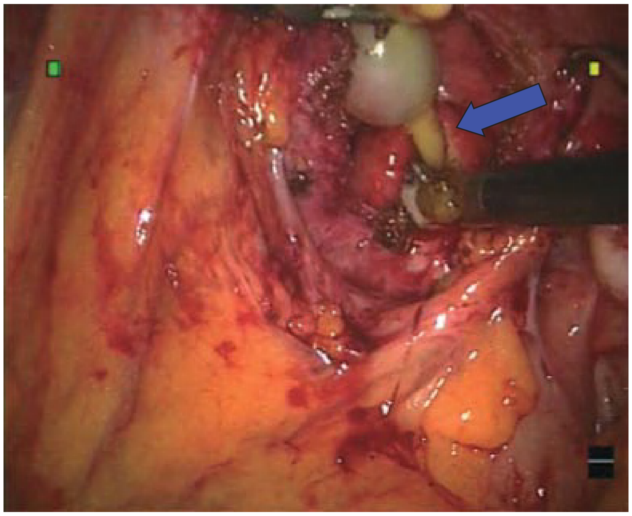

Figure 88.3 The Foley catheter passed through the fistula is pulled intra-abdominally through the cystotomy by holding its tip with grasping forceps, and is used to retract the anterior bladder wall, splinting open the cystotomy to allow better visualization of the fistula (arrow).

In the case of repair of a fistula involving the cervix, a ureteral catheter preplaced into the uterus at the beginning of surgery helps in the accurate repair of the cervix without unduly narrowing the os [15]. Excessive narrowing of the os can lead to stricture of the cervical canal and hematometra. In a vesicouterine fistula, the uterus is closed with interrupted sutures using 3-0 polyglactin on a round bodied needle. Occasionally in these cases, hysterectomy may be needed [16]. While this can be performed with robotic assistance, the detailed description of the technique is beyond the scope of this chapter.

Combined repair of vesicovaginal and ureterovaginal fistulas

We have experience in repairing complex urinary fistulas, which includes repair of vesicovaginal and ureterovaginal fistulas [17, 18][8]. In case the fistula is too close to a ureteral orifice or if there is a coexistent ureterovaginal fistula, the distal ureter is identified at the level of the bifurcation of iliac vessels and mobilized using the robotic instruments described above. The dissection must be done with care, releasing the ureter from the often dense periureteral adhesions consequent to the previous surgery or urine leak but preserving the periureteral vasculature. With robotic assistance, excision of the terminal end of the ureter and ureteroneocystostomy are performed with 5-0 poliglecaprone (Monocryl) (Figure 88.4). If the ureteral defect is longer, the anasto-

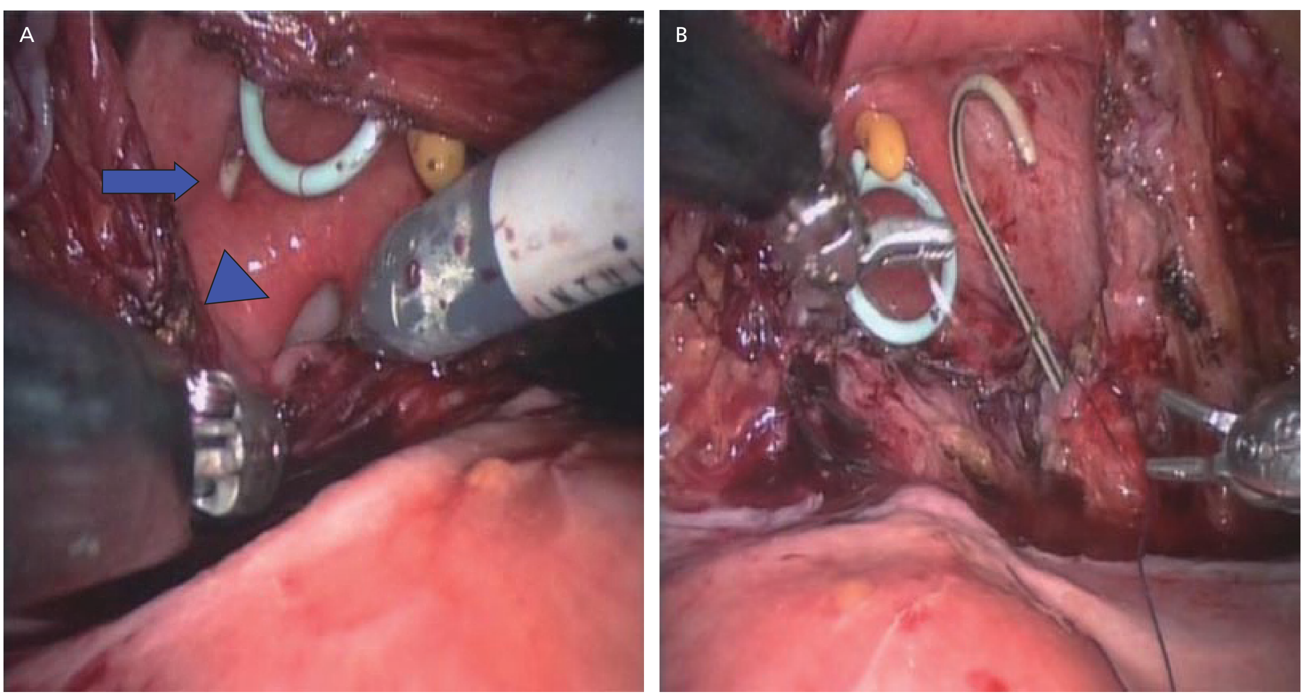

Figure 88.4 (A) Dissection of the vesicovaginal fistula and (B) right ureteral mobilization prior to reimplantation, in the same patient. The arrow shows the left ureteral orifice with the stent *in situ* and the arrow head shows the fistulous opening being circumscribed.

mosis can be facilitated by performing a psoas hitch or by the use of a Boari flap, both of which can be performed robotically [18–20] as well as with pure laparoscopic techniques [21, 22]. All these steps are carried out intracorporeally. In a known case of multiple or combined fistulas, we repair vesicovaginal and ureterovaginal fistulas simultaneously (see Video 88.1).

Step 5: Exiting the abdomen

At the end of the procedure, the pneumoperitoneum pressure is reduced to 5 mmHg to look for any bleeding, which if found is controlled with diathermy. The primary 12-mm port is closed with 1-0 Vicryl. All other ports are closed with subcuticular poliglecaprone sutures. The perurethral Foley catheter is retained at the end of surgery. We do not place a suprapubic catheter.

Operating technique of laparoscopic repair of vesicovaginal fistula

The procedure for laparoscopic repair of vesicovaginal, vesicocervical, and vesicouterine fistulas is almost identical to the above, but with several important differences: instead of 8-mm ports, two 5-mm ports are used on either side of the rectus abdominis muscle for the laparoscopic instruments [15, 23, 24]. The surgeon stands on the left side of the patient and the assistant on the right.

Postoperative care

Intravenous fluids are continued until the evening of the day of surgery, and the patient is allowed sips of water in the evening and semisolid diet next day morning. Antibiotics are continued for 24 h after surgery. Parenteral ketorolac or morphine is administered for analgesia as per need. External intermittent pneumatic compression of the calf muscles should be continued until the patient ambulates, usually on the evening of surgery or the morning of the next day. Early ambulation is desirable to reduce the risk of venous thromboembolism.

The drain is removed on the first or second postoperative day, when the drainage is less than 30 mL in 12 h. Usually the drain is removed within 24 h. The patient is discharged following removal of the drain. Occasionally, a patient may require a stay of 48 h. The indwelling catheter is removed in 10 days and a cystogram may be performed if necessary prior to removal of the catheter. We, however, consider this is not necessary in most cases. When ureteral reimplantation has been done, the ureteral stent is removed 3 weeks postoperatively in the outpatient clinic using a flexible cystoscope. The patient is advised to abstain from having sexual intercourse for 8 weeks.

Complications

Other than the complications arising due to anesthesia and immobilization, the specific complications include hematuria due to primary or reactionary hemorrhage. Blood clots can block the catheter, increasing the intravesical pressure and the strain on the suture line in the bladder. The possibility of bacteremia due to an unnoticed preoperative infection should also be borne in mind if pyrexia occurs within 24 h of surgery. Urinary tract infections acquired postoperatively can present with fever on the second or third day . The case should also be evaluated to rule out deep vein thrombosis if there is hectic fever 3 to 4 days after surgery. Appropriate antibiotics as guided by culture reports are necessary to control and curb the infection to ensure sound healing.

Few complications specific to laparoscopy have been reported in the literature on vesicovaginal fistula repair. Nevertheless, it is reasonable to expect complications similar to those described in other laparoscopic procedures. These may include injuries to the bowel, mesentery, and blood vessels, like the inferior epigastric vessels, iliac vessels, aorta or the inferior vena cava. In addition, the ureter may also be injured during separation of the bladder and the vagina, and so great caution must be exercised during this dissection.

Results of surgery

In 1996, Nezhat *et al*. described the first laparoscopic repair of vesicovaginal fistula [25]. Since then there have been 16 reports of laparoscopic vesicovaginal fistula repair. The current literature on laparoscopic repair of vesicovaginal fistula is summarized in Table 88.1 [26–37]. These show that these procedures are feasible, effective, and safe in experienced hands. The hospital stay is shortened and the estimated blood loss is in the range of 100–150 mL in most series. Operating times are typically in the range of 180–240 min, but decrease with increasing experience. The larger series show a failure rate of about 8–12%. Although these techniques were initially used predominantly for the repair of posthysterectomy vesicovaginal fistulas and postcaesarean uterovesical fistulas [38], recent series indicate that with experience these techniques can be used to treat the more complex obstetric fistulas also [27, 32]. The current literature on robot-assisted laparoscopic repair of vesicovaginal fistula is summarized in Table 88.2 [39–43]. This shows that it is feasible, safe, and carries a low morbidity. The hospital stay is short and the estimated blood loss is less than 150 mL. The operative times also show a decreasing trend in recent series as compared to older ones. Robot-assisted laparoscopic repairs have been done on both obstetric as well as gynecologic fistulas.

Robot-assisted laparoscopic repairs of pure reimplantation of the ureter for posthysterectomy ureterovaginal fistulas [17], as well as repair of vesicovaginal fistula repair combined with ureteric reimplantation, have been reported (personal communication). There is as yet no report of enterocystoplasty or treating a radiation-induced fistula using these minimal access techniques. However, with increasing experience and better instrumentation, more and more complex fistulas are likely to be repaired using these minimal access techniques in the future.

Conclusions

Laparoscopic techniques with or without robotic assistance are being increasingly used for the repair of vesicovaginal fistulas. Although these minimally invasive procedures are challenging with a fairly steep learning curve, it is now established that they are safe and effective in vesicovaginal fistula repair, and have the benefits of short hospital stay, lower need for analgesics, lower blood loss, and faster convalescence. They can be performed by any urologist trained in laparoscopic/robotic surgery. While many advantages of minimal access techniques in vesicovaginal fistula repair are now established, the cost-effectiveness of these techniques will vary in different regions and merits evaluation. Robotic assistance makes intracorporeal suturing much easier, thereby facilitating reconstructive procedures like vesicovaginal fistula repair. However, the very high cost of the surgical robot has restricted the widespread adoption of this minimally invasive technique for the repair of vesicovaginal fistula.

[2]Department of Urology, Inje University College of Medicine, Haeundae-gu, Busan, Korea

Introduction

In the early 1990s, attempts were made by urologists to conduct extirpative and reconstructive procedures using laparoscopy. The first reported laparoscopic cystectomy was by Parra *et al*. in 1992 for pyocystitis [1] and the first laparoscopic radical cystectomy for malignancy was completed by Sanchez *et al.* in 1993 [2]. With the development of instrumentation, skill, and expertise, applications of laparoscopy have expanded to more bladder procedures, such as partial cystectomy, bladder augmentation, and appendico-vesicostomy.

The turn of the century saw a surge in laparoscopy with robotic assistance. Laparoscopy in itself has the benefit of improved vision, especially in the narrow spaces in the abdomen. The entry of robotics enhanced the benefits of laparoscopy. Three-dimensional (3D) high-definition imaging, elimination of tremors, ergonomic positioning of the surgeon, and the EndoWrist™ have redefined minimally invasive surgery, and the benefits they bring clinically translate to shorter operative times and less blood loss. On the downside, the use of the robot has escalated cost, but with continuing technologic advances, robotics is here to stay. As with conventional laparoscopy, procedures conducted robotically have also expanded to include various bladder surgeries.

As the operative techniques for conventional laparoscopy and robot-assisted laparoscopy are generally the same, the techniques covered in this chapter are thus discussed collectively.

Partial cystectomy and diverticulectomy

Indications and background

Radical cystectomy is the standard treatment for recurrent, high-grade, organ-confined, muscle-invasive bladder carcinoma [3–5]. Recognizing the debilitating effects of this procedure, bladder-preserving techniques have been proposed. An ideal candidate for partial cystectomy is a patient with a first-time recurrence of a solitary tumor located in the bladder in whom a 1–2-cm margin will be feasible and whose bladder has normal function and capacity [6]. Since local control has been questioned, adjunctive radiation and/or chemotherapy have been attempted. With limited results, it still has not been widely accepted and may therefore be utilized for a select group of patients only. It may be offered to patients with severe comorbidities and those who refuse total cystectomy with appropriate advice regarding long-term results. A concomitant pelvic lymph node dissection is also advocated in all cases of urothelial carcinoma.

For patients with urachal adenocarcinoma that involves the bladder dome, partial cystectomy is also indicated [7]. A number of studies have shown the feasibility of the minimally invasive approach for this indication (see Results below).

Diverticulectomy of the bladder is an accepted procedure as weakness in the bladder wall at these outpouchings interferes with complete voiding. Other accepted indications for bladder diverticulectomy include large

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

and symptomatic diverticula associated with lithiasis, cancer, recurrent infections, and those causing ureteral reflux or obstruction [8]. Laparoscopic and robot-assisted approaches have been proven to be feasible and safe (see Results below).

Operative technique

Patient positioning

The patient is placed in the lithotomy position with all pressure points padded. Arms, legs, and chest are secured to the operating table (Figure 89.1). The hips are hyperextended and the table tilted to a low-to-steep Trendelenburg.

1. Port placement and instruments

Initial access may be via the Veress or Hasson technique. For conventional laparoscopy, a five- or six-port configuration is used, similar to laparoscopic prostatectomy (Figure 89.2A). With the use of the robot, a five- or six-port configuration is used, similar to robot-assisted

Figure 89.1 Initial patient position. Patient in lithotomy with chest, arms, hands, and legs padded and secured.

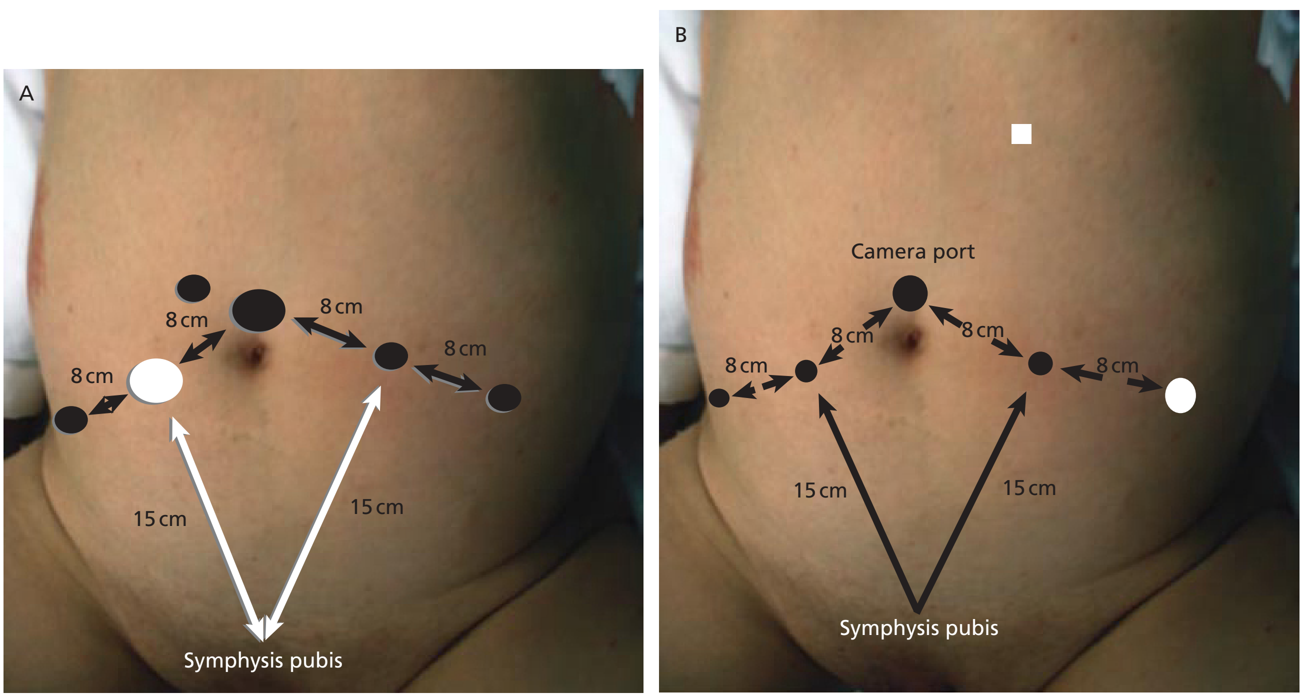

Figure 89.2 (A) General conventional laparoscopic bladder surgery port placement: A 12-mm supraumbilical camera port, three 5-mm ports, and a 12-mm working port (white circle). (B) General robotic bladder surgery port placement: a 12-mm supraumbilical camera port, three 8-mm robot ports, a 12-mm assistant port (white circle), and a 5-mm assistant port (white square).

laparoscopic prostatectomy utilizing four robot arms. (Figure 89.2B). The fourth arm may be used on the right or left depending upon the surgeon's preference. At least one assist port (12-mm trocar) should be used for entry and exit of sutures, and suctioning. The camera port is placed supraumbilical. For cases of urachal cancer, it should be placed about 3–5 cm cephalad to the umbilicus.

The conventional laparoscopy instruments are grasping forceps, monopolar scissors, ultrasonic shears or J-hook electrocautery. Robotic instruments are bipolar forceps, monopolar scissors, needle driver, and optional grasping forceps for the fourth arm.

Steps of the procedure

Partial cystectomy

Upon insertion of the laparoscope, the abdomen is inspected for any abnormal or unusual findings. Any small or large bowel adhesions to the bladder are released as necessary.

The peritoneum is incised lateral to the medial umbilical ligaments, dividing it close to the urachus and dissecting down to the pubis. For urachal cancer, resection is performed more cephalad up to the umbilicus, and should include the posterior rectus sheath.

The bladder is incised about 2 cm from the presumed site of the tumor circumferentially. The specimen is then placed in an entrapment bag for later extraction. For bladder adenocarcinoma, the resection should be wide and include the urachal remnant.

Using a 2-0 absorbable suture such as Vicryl, the bladder defect is repaired in two layers. A continuous or interrupted technique may be used, depending on the surgeon's preference, as long as a watertight repair is achieved. The bladder is then distended with 150–200 mL of saline to check for leaks.

Pelvic lymph node dissection is advocated for all cases of bladder carcinoma to adequately stage the disease. Some authors prefer to conduct the lymphadenectomy prior to releasing the bladder and cystotomy to minimize handling of local tissues after the bladder is opened [9]. The technique is the same as described below for lymph node dissection during radical cystectomy. A drain is inserted and all instruments are pulled out. The specimen is delivered through the umbilical port with enlargement if necessary. Fascia repair is done on all ports larger than 8 mm. Subcutaneous tissue and skin closure are the final procedures.

Bladder diverticulectomy

After the ports are placed, all bowel adhesions to the bladder are released. Under direct vision of the laparoscope, cystoscopy in then performed.

The diverticulum is identified. It has been proposed that a urethral catheter [10] and angiocatheter [11] are inserted into the diverticulum for distention and identification intraperitoneally. Alternatively, via cystoscopy, a Collings knife is used to circumferentially mark or resect the diverticulum with a 1-cm margin, also under direct visualization through the robot camera port in the abdomen [12].

The bladder and diverticulum are inflated. Overlying peritoneum and fat are dissected. The diverticulum is then resected at its base with a margin of about 1 cm. The specimen is placed in an entrapment bag for later extraction.

Bladder repair and finishing are as described above.

Tips and tricks

During preoperative evaluation, multiple bladder biopsies should be taken to rule out multifocal disease or presence of carcinoma *in situ*, which are contraindications to partial cystectomy.

Care should be taken during resection in close proximity to the ureters as inadvertent injury may occur. If deemed necessary, ureteral stents may be inserted to aid in identification.

As diverticula commonly occur due to chronic obstruction, relief of the antecedent obstruction should also be done, but there is no clear consensus on whether this should be done before or after the diverticulectomy. However, if the diverticulectomy is done first, an endoscopic procedure after repair is ill-advised as bladder distention may weaken the repair.

For resections of the dome of the bladder, it is safe to clip the superior vesical artery to prevent excessive bleeding during the procedure and allow adequate mobilization of the bladder.

In high-risk disease, multimodal treatment can be used, such as preoperative chemotherapy and possible radiotherapy [6].

One issue with partial cystectomy is tumor seeding once the bladder has been opened intraperitoneally. Haddad *et al.* suggested the use of preoperative irrigations of intravesical chemotherapy [13]. However, this has not been generally accepted or practiced due to limited data. Spillage of urine or fluid during or after cystotomy should be avoided. Port site metastasis is also an issue but there is little data on its occurrence.

Frozen section analysis of bladder margins may be performed to ensure adequate margins.

Postoperative care

A drain may be kept for at least 24 h to evacuate secretions due to the dissection or aid in early identification of cystorrhaphy leaks. The Foley catheter is kept indwelling for 7–10 days. A cystogram may be done to

confirm a healed bladder prior to removal of the catheter.

Complications

The most probable complication is urine leakage from the bladder repair. However, with a well-conducted repair, this should not be expected. A water-tight repair can be confirmed intraoperatively by inflating the bladder with 150–200 mL of normal saline. If present though, it can usually be managed by maintaining an indwelling Foley catheter for longer than usual. Other possibilities include bleeding, infection, voiding dysfunction, and postoperative adhesions. Infection can be prevented by ensuring sterile urine, especially in patients who are chronically obstructed and have large diverticula. Bleeding is easily identified with the vision provided by the laparoscope and the majority of bleeds are controlled by the cystorrhaphy. Bladder capacity is dependent on the amount of bladder tissue resected. As with any abdominal surgery, adhesions may develop and may result in intestinal obstruction.

Results

The majority of studies on laparoscopic partial cystectomy are on nonurothelial tumors. Chan *et al*. and Wadhwa *et al*. reported on urachal adenocarcinoma [14, 15]. The study of Nerli *et al*. involved two cases of urachal adenocarcinoma and one case of transitional cell carcinoma [16]. Follow-up after 24.6 months did not reveal any recurrence. Tai *et al*. reported four cases: one bladder endometriosis, one leiomyoma, one urachal adenocarcinoma, and one urothelial carcinoma within a diverticulum [17]. The one case of urothelial carcinoma had a recurrence after 3 months at a different site, which was managed by endoscopic resection. Follow-up after 12 months did not reveal any recurrence. Marino *et al*. have reported the only study solely on transitional cell carcinoma of the bladder managed by laparoscopic partial cystectomy [9]. Of six patients histopathologically staged from pT1G3 to pT3aG3, one had local recurrence with accompanying distant metastasis to the bone and liver 9 months after partial cystectomy. They did not, however, mention which patient had the recurrence. A summary of the results of these studies is given in Table 89.1.

Robot-assisted partial cystectomy has been utilized for both benign and malignant conditions. Although data are few, results have been positive. A number of series have shown the feasibility and safety of robotic application in partial cystectomy and diverticulectomy for benign tumors, diverticulum, and endometrial infiltration into the bladder [18–21]. Tareen *et al*. reported four cases: two benign bladder masses, one inflammatory diverticulum, and one urothelial carcinoma within a diverticulum [19]. Their results showed no intraoperative complications, acceptable operative time, and neg-

TCC, transitional cell carcinoma.

ligible blood loss. Myer *et al*. reported successful concomitant ureteral reimplantation for a Hutch diverticulum [20]. The first report of robot-assisted partial cystectomy for bladder cancer was by Allaparthi *et al*. [22]. In this series of three patients, results were comparable to laparoscopic series and no intraoperative complications occurred, but one patient was readmitted due to bowel obstruction. No recurrences were observed over a median follow-up of 6 months.

Results of robotic application are few and short term. As more cases are conducted, sufficient data may be presented to finally determine the benefits of robot assistance in partial cystectomy and diverticulectomy.

Pelvic lymphadenectomy

Indications

Pelvic lymphadenectomy (PLND) here is discussed in the context of bladder carcinoma as it is an integral part of radical cystectomy. Not only is it important in adequately staging the disease, but studies have also shown it to benefit survival, especially when an extended template is used, resulting to more nodal yield [23–25]. Finelli *et al*. showed that laparoscopic PLND was feasible with enhanced nodal yield [26]. It is likewise advocated in cases of partial cystectomy for urothelial carcinoma.

Operative technique

Patient positioning

The patient is secured to the operating table in lithotomy and titled to a steep Trendelenburg position.

Port placement and instruments

A five- or six-port configuration is done similar to laparoscopic partial cystectomy.

For the robot-assisted transperitoneal approach, a six-port configuration is used, similar to that for partial cystectomy. The 12-mm camera port is placed 2–3 cm cephalad from the umbilicus at the midline. Two 8-mm ports for the left and right robot arms are placed 8 cm lateral from the midline and 15 cm from the upper border of the symphysis pubis. Another 8-mm port for the fourth robot arm is placed 8 cm lateral from the right robot arm. A 12-mm assist port is placed 8 cm lateral to the second robot-arm port. Lastly, a 5-mm assist port is placed 9–10 cm from the camera port in a plane midway between the camera and left robot port. This configuration is for a right-sided fourth arm with the assistant on the patient's left. It may be modified to the reverse position according to the surgeon's preference.

The instruments used are a 0° or 30° lens, bipolar forceps, monopolar scissors, grasping forceps, laparoscopic forceps, and suction probe

Steps of the procedure

Upon entry of the laparoscope, the abdomen is inspected. Any bowel adhesions to the lower gutters of the abdomen should be released to allow the intestines to fall back into the upper abdomen. The proximal part of the dissection is carried out prior to releasing the bladder. Releasing the bladder early may reduce the working space, especially in a small pelvis. Alternatively, or in cases of large bladder tumors, the node dissection may be done after the cystectomy.

The procedure is started on the left side. The posterior peritoneum is incised lateral to the sigmoid colon. The ureter is dissected and retracted laterally, while the colon is retracted medially. The peritoneum is further dissected down to the ureterovesical junction (UVJ). This exposes the common iliac vessels which are skeletonized down to the internal iliac branch (Figure 89.3). If an extended dissection is desired, the peritoneum is incised further toward the distal segment of the descending colon. The colon can then be retracted further to expose the aortic bifurcation. Nodes in this area, including the presacral area, can thus be extracted. A similar procedure is conducted on the contralateral side. The bladder is then released as in the usual transperitoneal prostatectomy/cystectomy technique. This exposes the external iliac vessels. The vas deferens is retracted and

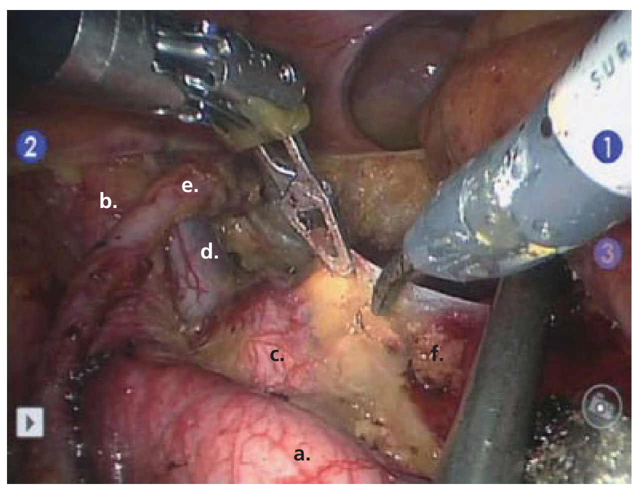

Figure 89.3 Extended pelvic lymph node dissection. After incising the peritoneum, the rectum is retracted contralaterally and the ureter is dissected revealing: a., left common iliac artery; b., left external iliac artery; c., left internal iliac artery; d., left external iliac vein; e., left ureter; and f., presacral area.

the iliac vessels are skeletonized from the anterior abdominal wall down to the iliac bifurcation. In the area of the proximal external iliac vessels, the obturator vessels can be identified and preserved. When persistent bleeding is encountered from the obturator vein, it may be sacrificed. Often, there is a perforating tributary of the obturator vein to the pelvic side wall inferolateral to the obturator nerve. Care must be taken in this area since it may also result in persistent bleeding once injured. A similar technique is conducted on the contralateral side.

Tips and tricks

Judicious use of cautery or hemostatic clips is warranted during dissection as much oozing may be experienced from small vessels. Although the amount of bleeding may be insignificant, it affects good visualization of the field.

Postoperative care

Closed suction drains are important for the drainage of secretions due to the dissection and also for cases with lymphorrhea. Aside from perioperative prophylactic administration of subcutaneous heparin, early ambulation or mobilization of the lower extremities also contributes to the prevention of thrombus formation.

Complications

As the dissection is in close proximity to blood vessels and nerves, injury to these structures is always a possibility. Preventive measures include anatomic dissection and careful use of sharp dissection and electrocautery. Minor vessels may be clipped. Injury to major vessels should be repaired. Pneumoperitoneum and manual tamponade can limit bleeding initially. An appropriate repair can subsequently be done with vascular sutures. Bowel and ureteral injuries may also occur during dissection. Immediate identification is crucial as they may lead to peritonitis, urinoma, and sepsis. If identified early, they may be repaired primarily; ureteral injuries will require a double-pigtail stent.

Another complication of lymphadenectomy is lymphocoeles. Although a transperitoneal approach may be associated with a lower incidence, it still may occur. It is still controversial whether intervention is warranted for asymptomatic lymphocoeles; however, symptomatic ones usually necessitate treatment ranging from percutaneous drainage to laparoscopic or open drainage.

Deep vein thrombosis may also occur. Preventive measures include prophylactic administration of heparin and compression devices.

Results

PLND is an integral part of radical cystectomy and is generally accepted in partial cystectomy. The current issue is the extent of dissection deemed necessary. Standard dissection includes the following borders: lateral – , genitofemoral nerve;; medial – bladder; cephalad – bifurcation of the common iliac artery; and caudal – endopelvic fascia. The current trend is to consider an extended dissection as some studies have shown survival benefit [23–25]. This appears logical as some studies have shown skip nodal metastasis [24]. In addition, the report by Capitiano *et al*. showed that analysis of 45 nodes resulted in 90% detection of nodal metastasis, whereas analysis of another 25 nodes resulted in 75% [27]. Although there are conflicting studies and randomized controlled trials are not yet available, an extended dissection is the best management option at this time from an oncologic point of view.

As minimally invasive surgeons have gained skill and confidence with continued use, conventional laparoscopic and robot-assisted approaches to PLND have proven to be feasible [26, 28] and results are comparable to those with the open technique.

Radical cystectomy

Indications and background

Radical cystectomy with PLND is still the standard treatment for muscle-invasive bladder carcinoma in the absence of metastatic disease and in some patients with refractory local symptoms in whom palliative surgical management may be necessary [29].

The minimally invasive approach for radical cystectomy is an attractive option due to the potential benefits of shorter convalescence, decreased morbidity, and improved health-related quality of life [30]. Perioperative outcomes of laparoscopic techniques generally show less blood loss and lower transfusion rates, shorter hospital stay, and earlier resumption of a regular diet. Short-term results are oncologically similar to those for an open technique, but long-term results are few.

As the procedure itself is technically difficult even with the open approach, substantial experience in laparoscopy is a prerequisite to a successful minimally invasive approach to radical cystectomy. Patient selection is also a critical factor to achieve acceptable, if not excellent, results. Organ-confined, low-volume disease is preferred as large tumors may limit the working space and wider excisions may be necessary in more aggressive disease. Multiple previous abdominal or pelvic surgeries may be considered only a relative contraindication as there have been reports of success with minimally invasive techniques in these groups of patients [31].

However, Yuh *et al.* reported that although previous lower abdominal surgery may not affect the likelihood of safe completion of robotic cystectomy, there is a higher risk for postoperative complications [32]. Obesity is likewise a relative contraindication as some report success even in these patients. Previous pelvic radiation therapy is considered by many to be a contraindication. Whether conventional or robot-assisted laparoscopy is better cannot be clearly delineated at this time. Results are few and short term, and there are no data from randomized controlled trials. At this time, the critical points for success in the minimally invasive approach to radical cystectomy are technical skill and experience, whether with conventional or robot-assisted laparoscopy, and patient selection. Which technique is better for urinary diversion will not be further discussed, but various studies have reported the feasibility of a number of approaches ranging from the typical ileal conduit to neobladders in both extracorporeal and intracorporeal access.

Operative technique

Patient preparation and position

Bowel preparation includes a mechanical and antibiotic component. Mechanical preparation may be done in the conventional 3-day format or a 1-day format with two doses of laxative (Phospho-soda®) on the day prior to surgery while the patient is on clear liquids and intravenous fluids. Nil per mouth is instituted on the evening prior to surgery. The antibiotic preparation includes 1 g of erythromycin and 500 mg of metronidazole every 8 h for three doses on the day before surgery and a third-generation cephalosporin 1 h prior to the operation.

The patient is positioned similarly to the position used for partial cystectomy and PLND.

Port placement and instruments

A transperitoneal approach is used. Port placement is similar to that described for PLND (Figure 89.2). The camera port is placed 2–3 cm caudal to the umbilicus. This set-up is also appropriate for extended pelvic node dissection and for sufficient dissection of the ureter proximally.

The instruments used are a 0° and 30° lens, bipolar forceps, monopolar scissors, grasping forceps, laparoscopic forceps, suction probe, metal and/or locking clips, and other hemostatic devices.

Steps of the procedure in the male

PLND may done before or after the bladder has been resected. We prefer to perform it initially to allow for clear isolation of the bladder's lateral pedicles during the dissection of the iliac vessels. During this time, the ureters are also dissected, which we believe saves more time, although this may be difficult when faced with a large bladder tumor.

The peritoneum is incised lateral to the sigmoid colon along the path of the common iliac vessels and down the pelvis along the ureter. The vas deferens is encountered, dissected proximally and distally, and transected. This allows for the dissection of the lateral pedicles as well as node dissection along the internal iliac chain. The ureter is dissected as far proximal as possible, preserving its blood supply, and then down to the UVJ. The ureter is clipped proximally and distally, and then transected. A segment from the proximal tissue should be cut and sent for frozen section analysis. After this dissection, the colon can be retracted towards the opposite side, giving a clear view of the aortic bifurcation down to the common iliac and its branches. Similar steps are conducted on the contralateral side.

The posterior peritoneum of the bladder in then opened and posterior dissection is performed, progressing caudally. The seminal vesicles and transected vas deferens are encountered and elevated. Posterior dissection is continued similarly to prostatectomy. The Denonvilliers' fascia is entered and dissection proceeds as close to the urethra as possible. Once posterior dissection is completed, dissection of the lateral bladder pedicles is then performed. The bladder is retracted to the contralateral side as the pedicles are dissected, clipped, and transected.

Next the bladder is released from the anterior abdominal wall. The peritoneum is incised lateral to the umbilical ligaments, the bladder dissected away from the rectus muscle, and the Retzius space developed. The peritoneum is transected at the area of the umbilicus. The endopelvic fascia is then opened and the pubo-prostatic ligaments transected. The anterior side of the prostate is cleared of all fat and the dorsal venous complex controlled with sutures or use of an endovascular stapler. The prostate is then dissected down to the urethra until it is ready for transection. In a nerve-sparing approach, dissection of the lateral prostatic fascia can be done, releasing the neurovascular bundle as conducted during prostatectomy. The dissection is continued from the prostatic apex to its base. The prostatic pedicles can then be controlled with the nerves safely out of the away. The urethra is clipped distal to the prostate to prevent spillage and subsequently transected. The specimen is placed in an entrapment bag. Lymph node dissection can now be done if not performed initially.

Tips and tricks

If nerve sparing is desired, care must be taken during dissection of the prostatic pedicles so as not to

inadvertently transect the neurovascular bundle. This may also occur during dissection lateral to the seminal vesicles.

Timing of the lymph node dissection is generally up to the surgeon's preference. An exception is when a large bladder tumor is to be resected as it may be safer to do this once the bladder is removed, due to the compromised working space.

The authors prefer the 0° lens during posterior dissection to facilitate visualization as caudal as the prostate–urethral junction. A 30° lens may be used for the other parts of the procedure.

Steps of the procedure in the female (anterior pelvic exenteration)

The infundibulopelvic ligament is identified superolateral to the ovaries. The overlying peritoneum is entered and the ovarian pedicles identified, dissected, clipped, and transected. The peritoneal incision is extended along the broad ligament toward the uterus and bladder. The round and cardinal ligaments are seen during this dissection, and are clipped and transected.

The ureters are then dissected as for the male patient. Partial node dissection is also an option at this time. The uterus is then retracted posteriorly while the bladder is maintained anterior. Peritoneum between these organs is incised and this space developed down to the cervix. The anterior vaginal wall is entered and transected on both sides, including the anterior third of the vagina in the specimen.

Lateral pedicles of the bladder are then controlled as described for the male patient. After this, the bladder is released and the retropubic space is developed. The endopelvic fascia is also opened. The dorsal venous complex is controlled and the urethra dissected to complete the urethrectomy. The specimen can then be delivered through the introitus. If orthotopic diversion is desired, the endopelvic fasica may be kept intact and the bladder transected precisely at the bladder neck. The Foley catheter is left in place, clipped, and transected to prevent spillage. The specimen is then placed in an entrapment bag.

The uterus is elevated and the transection just distal to the cervix is continued circumferentially, completing the hysterectomy. The specimen can again be delivered through the introitus or placed in an entrapment bag. The vagina is then reconstructed using a continuous interlocking stitch. If PLND has not been done initially, it may be done at this time.

Tips and tricks

Pneumoperitoneum may decrease from the time the vaginal wall is entered. However, the pelvis and the fixed placement of the robot trocars maintain an adequate working space. For this reason also, adequate hemostasis should be instituted prior to opening the vaginal wall.

There have been reports of prevention of loss of pneumoperitoneum with balloon devices, a sponge stick in the vagina, and temporarily suturing the vulva shut. Sears *et al.* reported the use of an anastomotic sizer modified with an occlusion balloon to preserve pneumoperitoneum [33], while Sabella *et al*. reported using a uterine manipulator with an adapted inflatable balloon inserted vaginally [34]. These techniques may be adopted during cystectomy to prevent or at least minimize gas loss.

Urinary diversion

Ileal conduit: extracorporeal technique

A 5–7-cm periumibilical incision is made, including the camera port site. In the male, the specimen is delivered. The dissected ureters are then identified and ureteral stents are placed. The left ureter is passed beneath the sigmoid colon to the right hemi-abdomen. The ileocecal valve is identified and a 20-cm segment of ileum is selected 20 cm from the valve. The ileal segment is harvested with its blood supply and the bowel continuity is restored. The proximal end of the conduit is closed in two layers. Two incisions on the antimesenteric border of the conduit are made about 2 cm apart. The stents are placed through these incisions and the ureteroileal anastomosis done with Vicryl 4-0. The ileostomy may be done on the port site of the right pararectus trocar.

Ileal conduit: intracorporeal technique

In the male, a 5-cm periumbilical incision is made, excluding the camera port site, to deliver the specimen. The abdomen is then closed and pneumoperitoneum reinstituted. A 20-cm long ileal segment is selected 20 cm from the ileocecal valve. The segment is isolated using a 60-mm endoscopic linear stapler. The bowel continuity is restored by a side-to-side anastomosis using a 60-mm endoscopic linear stapler. The ureteroileal anastomosis is performed with Vicryl 4-0, with stents inserted through the conduit into the ureters. The conduit is then pulled through the abdominal wall and anchored.

Orthotopic neobladder: intracorporeal technique

This technique may be conducted as described by Schumacher *et al*. [35]. A 50-cm segment of ileum is harvested. Once isolated, it is detubularized except for

the 10-cm proximal isoperistaltic Studer afferent segment. Bowel continuity is restored as described above. The urethra neobladder anastomosis is done first. A Van Velthoven technique is utilized, anastomosing the urethra at 10 cm from the distal end of the detubularized ileum with 10–12 stitches. After completing the anastomosis, the posterior of the Studer reservoir is closed using 3-0 synthetic absorbable suture. Half of the anterior part is then sutured. The ureters are then anastomosed to the proximal afferent segment using a Wallace technique. The remaining half of the anterior is then closed.

Orthotopic neobladder: extracorporeal technique

After the specimen is extracted via a 5–6-cm incision midway between the umbilicus and the symphysis pubis, the neobladder is constructed extracorporeally. A technique similar to open surgery may be used to create the neobladder: W pouch, double chimney, T pouch. Once completed, the neobladder is placed in the pelvis and a catheter inserted through the urethra into the neobladder. The abdomen is closed. Anastomosis can be done laparoscopically with or without robotic assistance. Two 3-0 synthetic absorbable monofilament sutures with an SH needle of about 15 cm in length are tied together at the ends. The anastomosis is conducted using a technique similar to the urethravesical anastomosis during laparoscopic or robot-assisted radical prostatectomy.

Tips and Tricks

After the conduit is constructed and the ureteroileal anastomosis completed, saline may be infused in the conduit to verify for leaks.

We advocate minimum but water-tight suturing in the ureteroileal anastomosis to prevent scarring and subsequent stricture formation.

The ureters should be checked for twisting and no tension should be present.

Complications

Radical cystectomy is one of the most extensive surgeries in urology. Hence, it is fraught with many possible complications. These include bleeding as the bladder is highly vascularized. The pelvic anatomy is likewise comprised of a host of blood vessels and nerve structures which could inadvertently be injured. Deep vein thrombosis is also a possibility due to the relatively long operative time and period of immobilization, as well as the risk associated with node dissection. However, preventive measures such as compression devices and perioperative heparin may be utilized. Bowel injury may also occur: rectal injury during posterior dissection, inadvertent injury to bowel falling into the operating field, and during harvest and construction of the urinary diversion. Failure to close the mesentery of harvested bowel segments may also lead to internal herniation. Urine leaks may also occur in inadequately closed urinary diversions.

Results

Worldwide experience in radical cystectomy has been increasing, with the total number of reported surgeries now amounting to more than 700 [36].

Laparoscopic cystectomy was compared to open radical cystectomy by Ha *et al*. in a nonrandomized retrospective study [37]. Comparing 34 cases of open to 36 cases of laparoscopic radical cystectomy, they found a longer operative time in the laparoscopy group, although this was not statistically different. On the other hand, estimated blood loss, transfusion rate, analgesic requirement, postoperative hospital stay, and required volume of infused fluid were less in the laparoscopy group. In another study by Porpiglia *et al*. comparing 22 open with 20 laparoscopic cystectomies, they found decreased postoperative narcotic requirement and shorter time to oral diet in the latter [38].

Table 89.2 shows selected studies on laparoscopic and robot-assisted radical cystectomy. Perioperative outcomes appear to be similar between the two techniques. Robotic application is relatively new and long-term outcomes are not yet available.

In comparing the minimally invasive approach to the current standard open radical cystectomy, oncologic outcomes and complication rates are of prime importance. The feasibility and safety of the procedure have been clearly established by a multitude of reports (Table 89.2). However, a more objective measure of the worth of a minimally invasive approach is based on oncologic principles. In an analysis of the largest laparoscopic series, Stephenson *et al*. reported a 0–7% positive margin rate, similar to those shown in Table 89.2 [48]. Herr *et al*. determined better survival rates in patients in whom more than 14 lymph nodes were extracted [49]. The studies in Table 89.2 show lymph node yield around this number also. In terms of survival rates, Hemal *et al*., who had the longest follow-up period at 38 months, observed a 73% disease-free survival rate [40]. Deger *et al*. noted a survival rate of 75% at a median follow-up of 33 months [50]. Cathelineau *et al.* reported the largest series at 84 cases, although 40 of these were prostate sparing. The survival rate was 83% at a mean follow-up of 18 months [41]. These laparoscopic cystectomy results equal those of the standard open technique. On the other hand, long-term results of robot-assisted radical cystectomy are still immature.

Table 89.2 Results of studies on laparoscopic and robot-assisted radical cystectomy.

Overall complication rates were noted to be higher in the intracorporeally performed urinary diversion compared to that performed extracorporeally (70% vs 22%) [51]. A significant difference in major complications requiring reoperation was also noted by Haber *et al.* between pure laparoscopic and laparoscopy-assisted urinary diversion (29% vs 11%) [52]. Some of these complications were related to the longer operative time of a completely intracorporeal approach. As Menon *et al.* showed that an extracorporeal approach to urinary diversion resulted to shorter operative times [45, 53], it seems logical to assume that this approach will result in fewer complications.

In a strict sense, comparing the results of studies using minimally invasive techniques with the standard open technique is inappropriate, since consideration should be given to the variety of techniques, patient selection, surgeon experience, and other sources of variance. However, it would also be unwise to neglect these results in the absence of properly done randomized controlled trials. The results are overwhelmingly encouraging despite the relative youth of the approach. The theoretical benefits of pneumoperitoneum, magnified vision, 3D in robotics, smaller incisions, and precise, controlled movements cannot be denied. In the coming years, these approaches may be generally accepted. However, technical skill and experience in minimally invasive surgery should also be emphasized in an extensive surgery such as radical cystectomy.

Augmentation cystoplasty

Indications

Bladder augmentation is indicated in patients with symptomatic, diminished bladder capacity and compliance in whom conservative treatment has failed. Contraindications include poorly functioning kidneys, renal tubular acidosis, liver failure, inflammatory bowel disease, short gut syndrome, and inability to perform intermittent catheterization reliably [54].

Operative technqiue

The patient is placed on a bowel preparation as described in the previous section. Port placement is similar to that for laparoscopic or robot-assisted laparoscopic cystectomy.

Steps of the procedure

A 20-cm ileal segment is harvested 20 cm from the ileocecal junction. Blood supply should be carefully preserved. The bowel continuity is then restored via endoscopic linear staplers or intracorporeal suturing. The 20-cm harvested segment is detubularized in its antimesenteric border. It is folded into a U-shape and the medial borders sutured with absorbable sutures in an interrupted fashion. The bladder is then filled with 150–200 mL of saline through the Foley catheter. The bladder dome is opened in the mid-sagittal and mid-coronal planes. The fashioned U-shaped segment is then anastomosed to the bladder with interrupted absorbable sutures. The bladder is again inflated to check for leaks in the anastomosis and reinforced accordingly. A drain is then placed in the pelvis.

Tips and tricks

Ureteral stents may be placed to help with identification during cystostomy and to prevent inadvertent injury.

The mesentery or blood supply of the harvested ileal segment should be of adequate length to reach the pelvis without tension.

Suture length may facilitate anastomosis. Elliot *et al.* in their laparoscopy study suggested 5–6 inches for interrupted suturing and 9 inches for continuous suturing [55]. Anastomosis can be tested by inflating the bladder with 100–150 mL of saline.

Complications

Associated complications include leakage, small bowel obstruction, metabolic and nutritional abnormalities, bladder calculi, and risk of malignancy relative to the bowel segment utilized for augmentation [56].

Results

Gill *et al*. described the first clinical experience on laparoscopic bladder augmentation [57]. They presented three patients with neurogenic bladder and augmentation done using the ileum, sigmoid, and cecum, respectively. Mean operative time was 6.76 h, estimated blood loss 150 mL, and hospital stay 5.33 days. A study by Rackley *et al.* on 12 patients also with neurogenic bladder reported a mean operative time of 7 h, estimated blood loss of 175 mL, and hospital stay of 5.7 days [58].

With robotic assistance, the study by Passerotti *et al*. described their technique utilizing the ileum in a swine model [59]. The first clinical description of an augmentation technique was presented by Al-Othman *et al*. [60]: operative time was 8 h and the patient was discharged on the fourth postoperative day.

Although these studies show the expansion of minimally invasive surgery to bladder augmentation, experience is still very minimal and requires high proficiency and technical capability in laparoscopy. Operative times are observably longer compared to open techniques.

Appendico-vesicostomy: Mitrofanoff procedure

Indications and background

Appendico-vesicostomy is the most widely used and reliable means of catheterizing the bladder through a channel when the urethra is not suitable [61]. It was originally described in 1980 in the management of neurogenic bladder [62]. Its continued use is due to its proven durability and few associated complications, as reported by the long-term analysis of Liard *et al*. [63].

As interest in minimally invasive surgery increased and experience in various procedures progressed, attempts at a laparoscopic and robot-assisted approach have been tried. Initial reports on the laparoscopic approach involved dissection of the bowel and harvest of the appendix, followed by an open reconstruction or the use of extracorporeal knots [64–67]. In 2004, the totally laparoscopic approach was reported by Hsu *et al*. and Casale *et al* [68, 69]. The use of robotic assistance was first presented by Pedraza *et al*. [70], followed by a few case reports and case series [71–73].

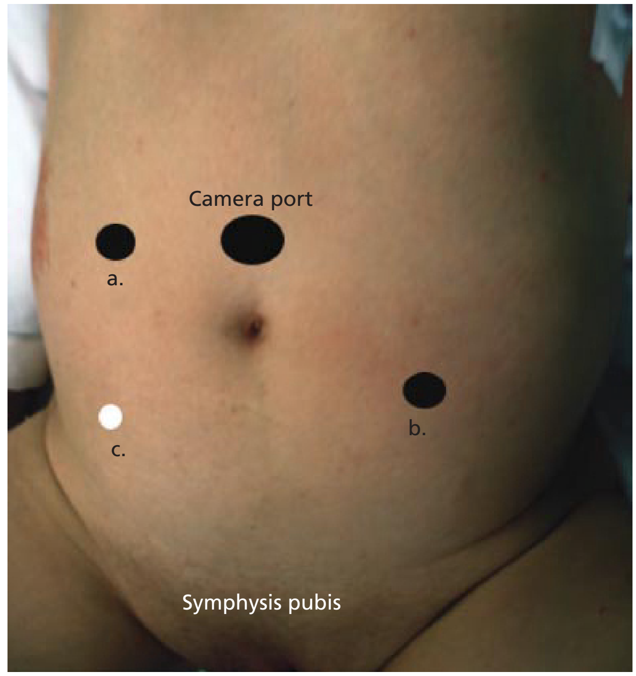

Figure 89.4 Port placement for appendico-vesicostomy. The camera port is placed more cephalic to the umbilicus. For conventional laparoscopy, a. is a 10-mm working port, b. is a 5-mm port, and c. is a 5-mm port, which is also used for the stoma. For robot-assisted laparoscopy, a. and b. are 8-mm robot ports, while c. is a 5-mm assistant port.

Operative technique

The patient is placed on a bowel preparation as described for radical cystectomy.

The adult patient is placed in a lithotomy position with the hips hyperextended and the table in a moderate Trendelenburg. Children are placed in a "frog legs" position. Port placement is described in Figure 89.4 for conventional laparoscopy and robot-assisted laparoscopy.

Steps of the procedure

The appendix is identified near the ileocecal junction. It is then dissected with the blood supply preserved. The appendix is then transected at its base with the cecal defect closed in two layers. A 8–10F feeding tube for pediatric and 14–16F for adults is inserted through the lumen of the appendix to confirm its patency. The peritoneum is incised over the anterior of the bladder. Using a technique similar to the Barry extravesical ureteroneocystostomy, two parallel incisions of diameter approximately equal to that of the appendix are made on the bladder without entering the mucosa. A submucosal tunnel is developed between the incisions, after which the mucosa on the distal incision is entered. The appendix is brought out through one incision through the submucosal tunnel, and sutured full thickness to the bladder mucosa at the 9, 3, and 6 o'clock positions. A horizontal mattress suture fixes and advances the appendix to the anterior bladder wall. The anastomosis is tested for leaks and ease of catheterization. The appendix is then externalized through the right lower quadrant trocar. Pneumoperitoneum is evacuated and the appendix stump sutured to the skin. A 10F or 16F silicone catheter is passed through the stump and into the bladder. A drain may or may not be left in the abdomen.

Tips and tricks

Mobilization from the cecum to the ascending colon along the line of Toldt may facilitate mobilization of the appendix with its blood supply towards the bladder and abdominal wall. There should be no tension in bringing the appendix to the skin.

The lumen of the appendix should be checked to ensure patency and adequate caliber.

A 5 : 1 ratio of tunnel length to appendix diameter may be used for the continence mechanism.

Complications

Postoperative complications associated with appendico-vesicostomy include infection, upper tract deterioration, stone formation, and most commonly stomal stenosis [61, 74].

Results

In two totally intracorporeal laparoscopic case reports, appendico-vesicostomy was done for pediatric patients with neurogenic bladder [62, 63]. Operative time was 198 and 360 min, discharge was on the third and seventh postoperative day, and follow-up after 8 and 9 months did not reveal any problems. Blood loss was mentioned in only one of the reports at 100 mL.

Case series on robot-assisted laparoscopic appendico-vesicostomy were reported by Storm *et al*. and Nguyen *et al*. [72, 73]. The first with three patients was published in 2007, and the second with 10 patients in 2009.: mean operative times were 301 and 323 min, estimated blood loss 50 and 48.4 mL, and hospital stay 3 and 5 days, respectively. There was one conversion due to an inadequate appendix in the second study.

These studies prove the feasibility and safety of laparoscopic and robot-assisted approaches to appendico-vesicostomy. Most of the studies, however, were conducted in the pediatric population. In the reports mentioned, there was only one adult case, a 45-year-old patient. Operative times in these studies are longer than with the open approach, although blood loss and hospital stay appear to be less. The benefit of minimally invasive techniques for this procedure still has to be proven conclusively.

CHAPTER 90
Laparoscopic Radical Prostatectomy

Jens Rassweiler,[1] Giovannalberto Pini,[2] Marcel Hruza,[1] Ali Serdar Goezen[1] & Dogu Teber[3]

[1]SLK-Kliniken Gmbh, Heilbronn, University of Heidelberg, Germany

[2]Policlinico di Modena, University of Modena, Modena, Italy

[3]Department of Urology, University of Heidelberg, Heidelberg, Germany

Introduction

In the USA more than 70% of radical prostatectomies are robot assisted using the da Vinci device (Intuitive Surgical, Sunnyvale, CA, USA). In Europe, there is skepticism concerning the ongoing spread of robotic systems, based on unfavorable experiences in orthopedics and cost pressures [1]. In Germany and Italy, 25% of radical prostatectomies are performed by laparoscopy (LRP). Advantages of this approach include reducing the access trauma, less pain and bleeding, and lower transfusion rates [2, 3]. Furthermore, all robot-assisted techniques are based on laparoscopy.

Historical background

In 1992, Schuessler attempted the first LRP [4]. However, his technique did not provide any advantages over retropubic radical prostatectomy (RRP) [5]. In 1995, Raboy *et al.* published a case of extraperitoneal LRP [6]. Gaston (personal communication) pioneered LRP in 1997, followed by Guillonneau, Vallancien and Abbou, who popularized the transabdominal access to seminal vesicles [7–10]. In 1999, Rassweiler *et al.* developed a retrograde technique similar to RRP [11, 12]. In the following years, several groups revisited the French technique [13–16], and in 2000, Bollens *et al*. revisited the extraperitoneal approach [17].

In 2002, a survey in Germany and Switzerland revealed that 15% of departments performed LRP, but only 5% did more than 15 cases per year [18]. In 2004, 19.2% of German departments were offering LRP [19]. In 2006, a multicenter study including 5800 patients treated by 50 surgeons was published [20]. In the USA, Gill was one of the few establishing a program of laparoscopic pelvic surgery [21, 22]. Menon initiated the change when hiring Vallancien and Guillonneau to establish LRP at his institution [23]. Perhaps more importantly, he invested in the da Vinci system and managed to perfect robot-assisted laparoscopic prostatectomy (RALP).

Indications and contraindications

Indications include men with localized prostate carcinoma and a life-expectancy of greater than 10 years [24]. All patients with stage less than T3, Gleason score less than 8, and prostate-specific antigen (PSA) less than 10 ng/mL are candidates for nerve preservation. Those with suspected extracapsular invasion (T3) or perineural invasion in core biopsies should not undergo nerve-sparing surgery (Table 90.1).

Previous transurethral resection of the prostate, abdominal or pelvic surgery, laparoscopic hernia repair, pelvic irradiation, and gross obesity can add to surgery complexity, and such patients should be approached only after considerable experience [25, 26]. Absolute contraindications are abdominal wall infection, generalized peritonitis, bowel obstruction, and uncorrected coagulopathy.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Anatomy of the prostate

Walsh *et al.* described three layers covering the anterolateral surface of the prostate: the prostatic fascia overlying the prostatic capsule and the levator fascia [27, 28], which fuse laterally to form the lateral pelvic fascia covered by the endopelvic fascia branching off the transversalis fascia. The Denonvilliers' fascia and prostatic capsule are posterior (Figure 90.1). The neurovascular bundles (NVBs) run along the posterolateral part of the prostate between the levator and prostatic fascia, and contain branches from the inferior vesical arteries running medial to the cavernosal nerve branches originating from the pelvic plexus. These vessels enter the capsule through the prostatic fascia. The nerves initially form a group about 12 mm wide and converge at the prostate level with a width of around 6 mm at the 5 and 7 o'clock position lateral to the urethra.

Table 90.1 Criteria for nerve sparing.

Clinical stage	
T1	When PSA is relatively low and the number of positive biopsies or the extent of biopsy involvement is limited
T2a	A contralateral nerve-sparing procedure can be proposed
T2b	A nerve-sparing attempt can result in positive surgical margins and give rise to local failure

Operative techniques

Four approaches have been described: (1) transperitoneal descending with initial dissection of the seminal vesicles [8]; (2) transperitoneal ascending [12]; (3) extraperitoneal descending [29, 30]; and (4) extraperitoneal ascending [31].

Patient positioning and trocar arrangement

The patient lies in a deflected supine position, with both arms parallel to the body with adducted legs (Figure 90.2A). A rectal balloon catheter is inflated with 40–60 mL of air. The operating table is placed in a 15–20° Trendelenburg. A 16F Foley catheter is inserted. Alternatively, a lithotomy position can be used (Figure 90.2B). Some authors prefer an incline of up to 30–40° [7, 32]. A semi-lunar or W-shaped arrangement of 5- and 10-mm trocars is recommended (Figure 90.3).

Access to the prostate

Transperitoneal access is accomplished with a Veress needle (maximum pressure 15 mmHg). The peritoneum is incised over both seminal vesicles and the vas deferens are exposed and divided. Thereafter, the space of

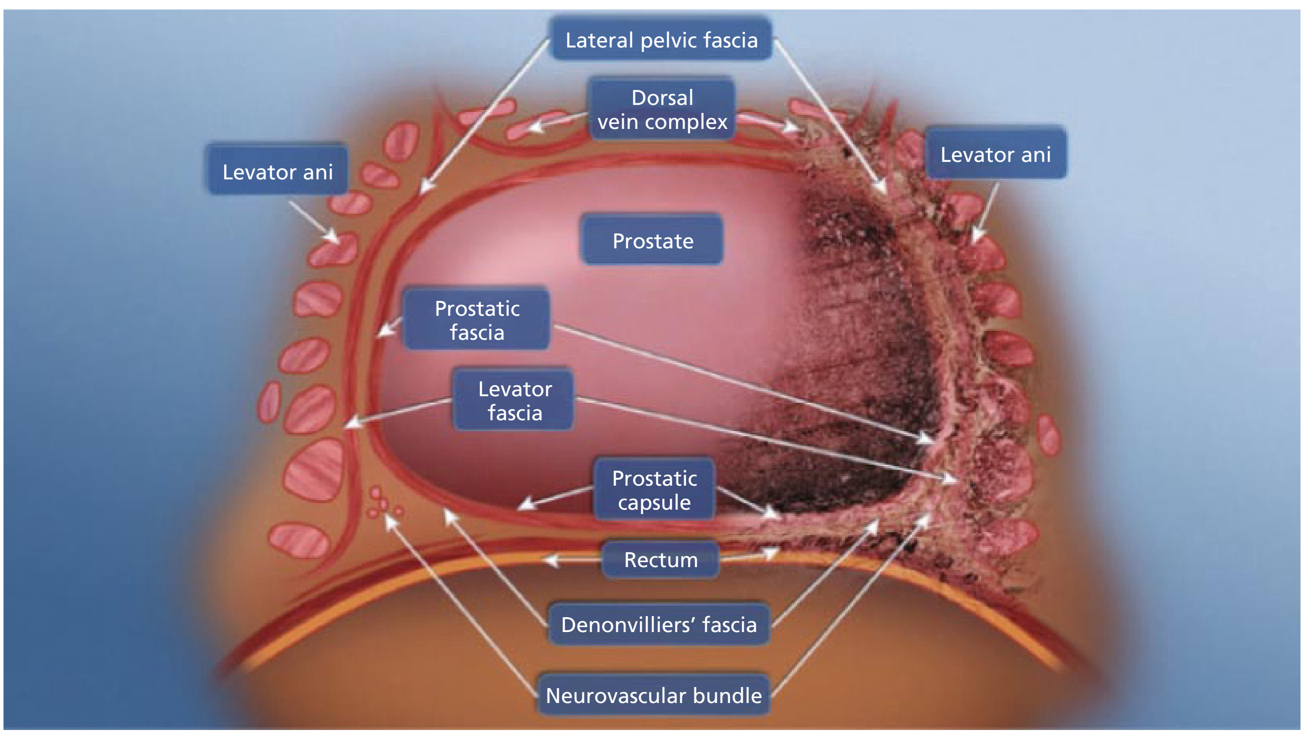

Figure 90.1 Fascial anatomy of the prostate according to Walsh *et al.* [27].

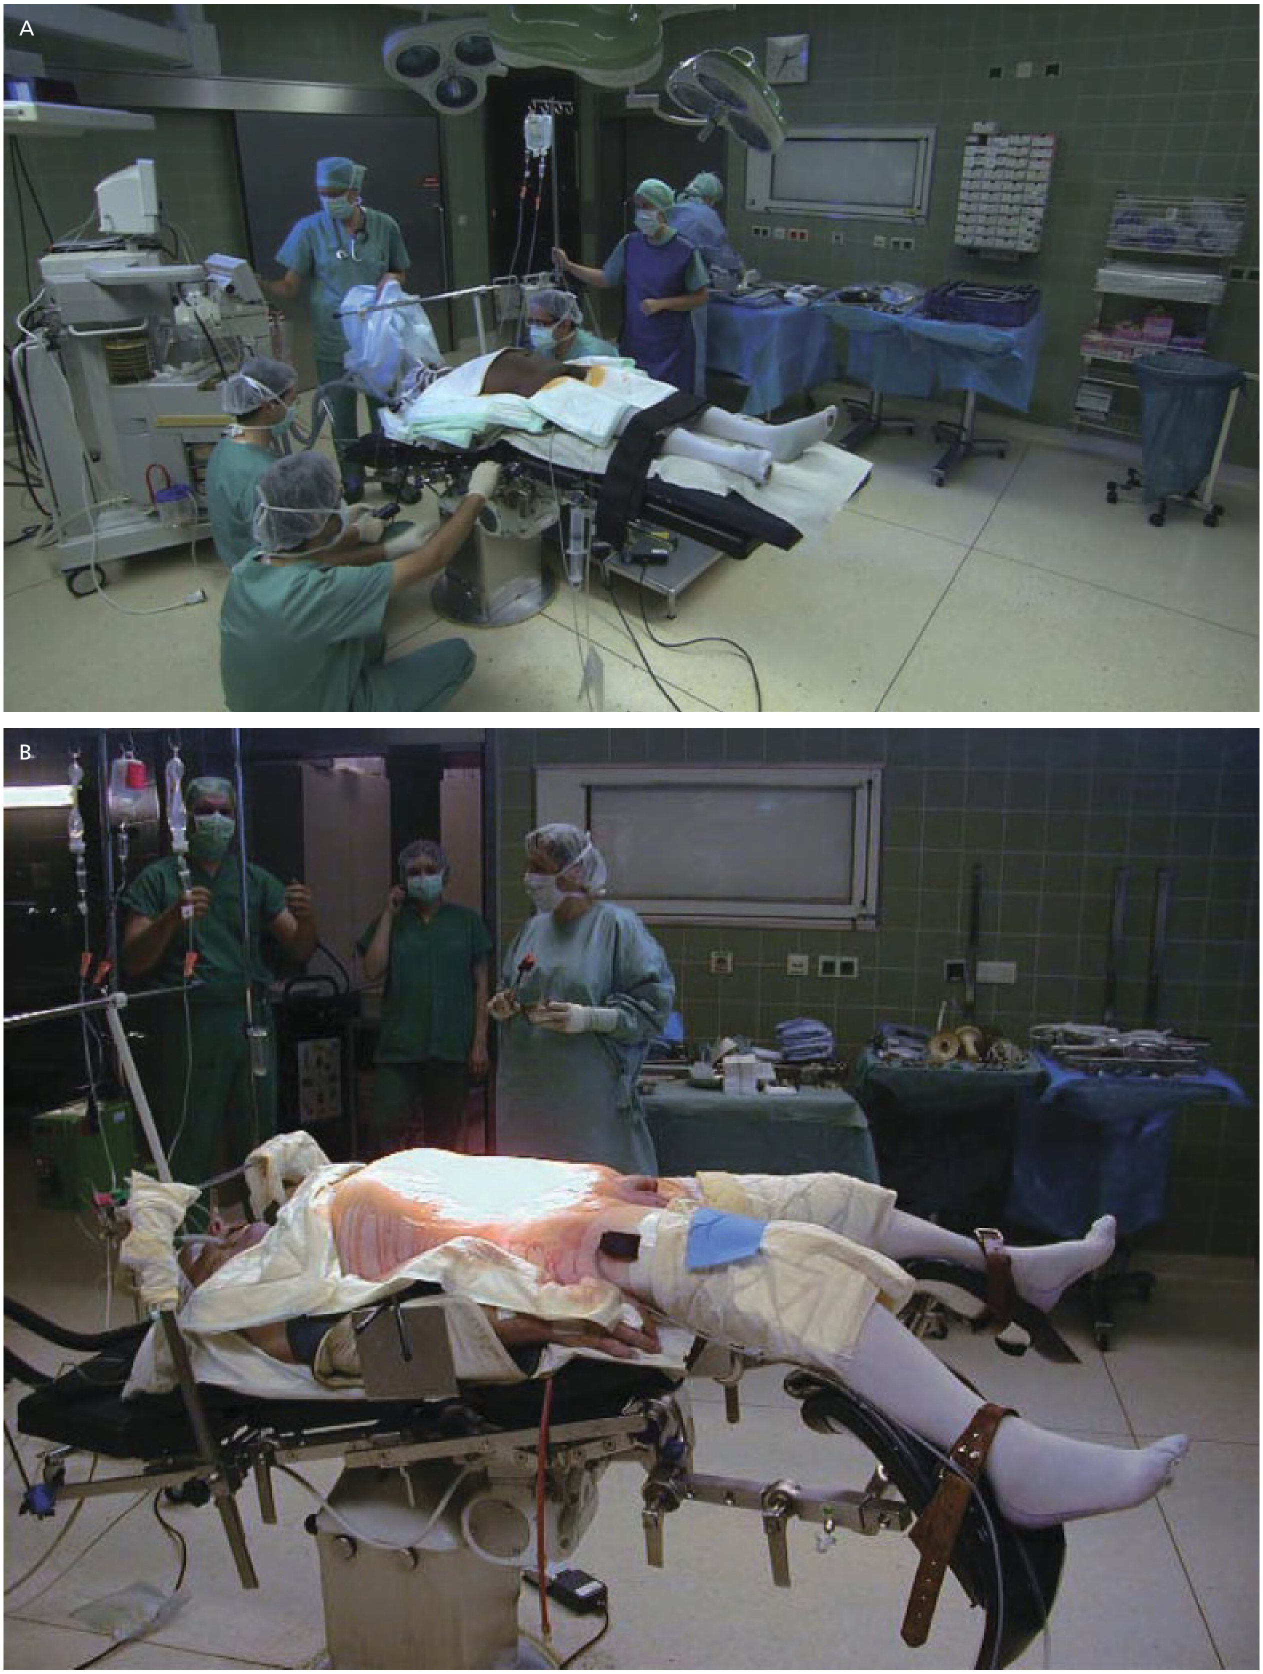

Figure 90.2 Positioning of the patient for laparoscopic radical prostatectomy. (A) Classic supine with adducted legs and 15–20° Trendelenburg (Heilbronn technique) . (B) Lithotomy position.

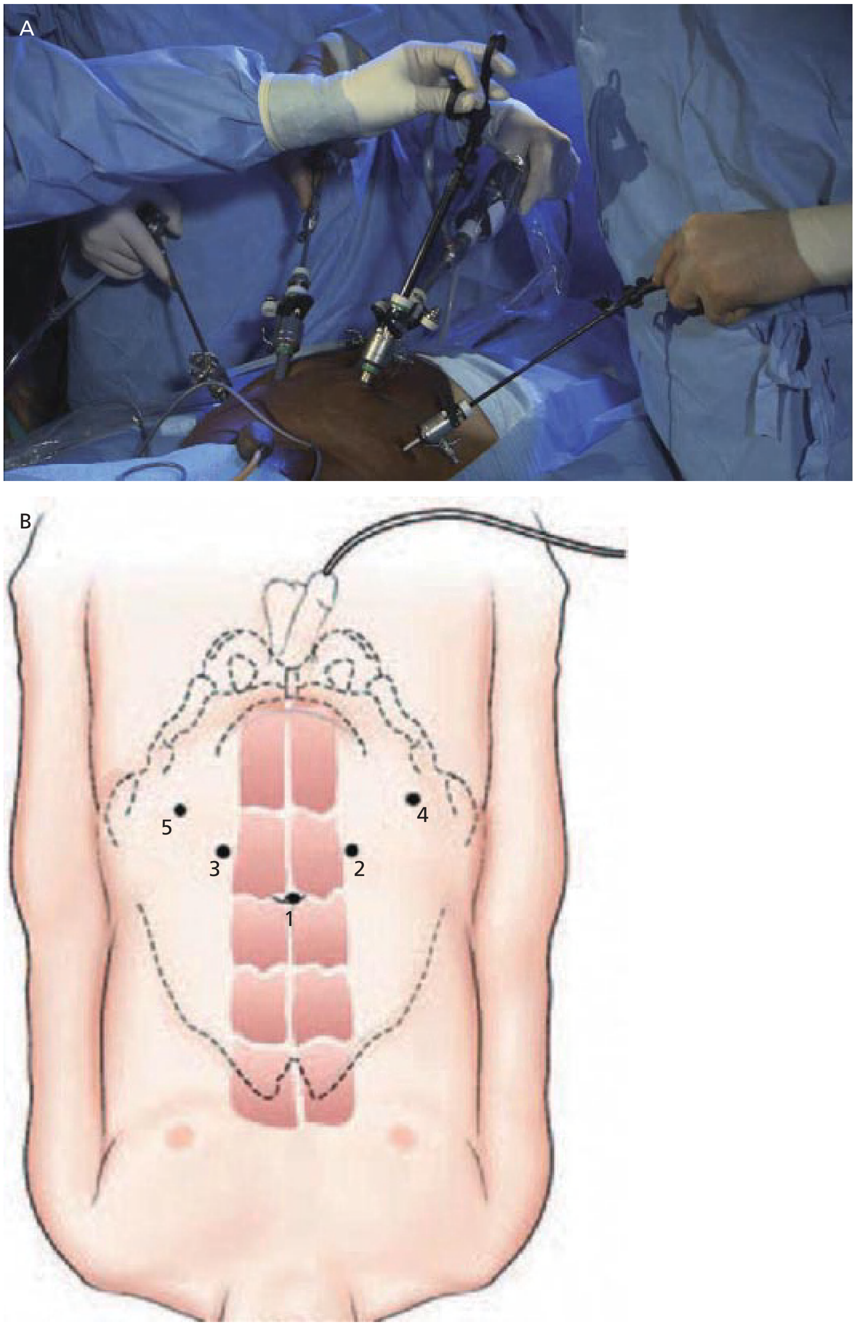

Figure 90.3 Trocar arrangement. (A) W-shape arrangement (Heilbronn technique). (B) Semilunar arrangement according to Ukimura *et al.* [22], reproduced with permission.

Retzius is developed by transection of the urachus after filling the bladder with 200 mL of saline.

Extraperitoneal access uses a periumbilical incision followed by extraperitoneal blunt dissection of the space of Retzius (balloon trocar; Figure 90.4). The other ports are placed after establishing the pneumo-extraperitoneum (maximum 12 mmHg).

Extraperitoneal versus transperitoneal approach (Table 90.2)

Transferability of the transperitoneal access was demonstrated [14, 31, 33, 34]; however, the extraperitoneal descending technique is easier to learn, as reflected in the shorter operating times [20, 35, 36]. Eliminating the

transperitoneal dissection of seminal vesicles may shorten operative time by 50 min [37]. Comparable surgical results between extraperitoneal and transperitoneal LRP have been published [31, 37–41]: some authors emphasize the advantages of the extraperitoneal approach (i.e. no bowel lesions, ileus, and peritonitis) [37, 39]; while others found no differences [31, 38].

Routes of dissection

The antegrade technique starts at the bladder neck. The Foley catheter is used as a retractor to expose and cut the posterior wall of the bladder neck (Figure 90.5A). Subsequently, the vesicoprostaticus muscle is divided, exposing the vas deferens and seminal vesicles. Using the vas as a retractor, Denonvilliers' fascia is incised to dissect the posterior surface of the prostate. Proximal pedicles are clipped and divided (Figure 90.5B). Following apical dissection the dorsal vein complex (DVC) is sutured and divided. Finally, the urethra is transected (Figure 90.5C).

The retrograde technique starts at the apex with suturing and dividing of the DVC. Thereafter, the urethra is incised (Figure 90.6A). The Foley catheter is used as a retractor during prostatic posterior dissection (Figure 90.6B). Subsequently, it serves as a retractor to expose the bladder neck, which is incised to reach the vas and seminal vesicles and to control the proximal pedicles (Figure 90.6C).

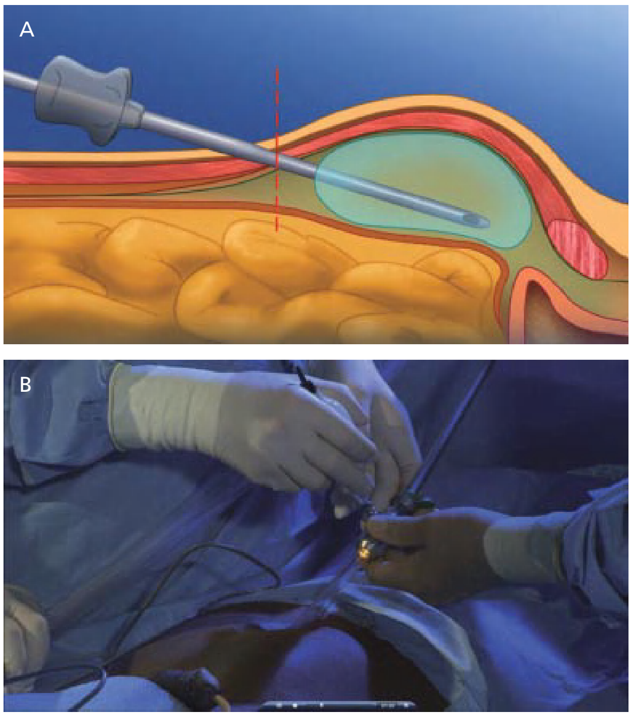

Figure 90.4 Balloon dissection of the space of Retzius under endoscopic control. (A) Schematic view. (B) Introduction of the telescope via the balloon trocar.

Retrograde versus antegrade technique

While the retrograde technique is more popular in open surgery [27, 42], laparoscopic and robotic surgeons favor the antegrade approach [33, 43]. The early control of prostatic pedicles and late division of the DVC ensure minimal bleeding.

Technical aspects for early continence

Long-term continence exceeds 90% in most laparoscopic and robotic series; however, early continence (i.e. at 3 months) is still in the range of 40–50% [3]. Several strategies have been proposed:

- Preservation/reconstruction of the puboprostatic ligaments;
  - Suspension of the DVC;
- Dissection of a long urethral stump;
- Preservation of the bladder neck;
- Preservation and reconstruction of the rectourethralis muscle.

Table 90.2 Advantage and disadvantage of extraperitoneal versus transperitoneal laparoscopic radical prostatectomy.

Advantages extraperitoneal		Advantages transperitoneal
No contact with bowel		Larger room
Previous abdominal surgery		Less tension on anastomosis
Fewer problems with urine extravasation		Minimal risk of lymphocele in case of extended lymph node dissection
Gross obesity		
Simultaneous inguinal hernia repair		
	No advantage one technique over the other	
	Operating time	
	Morbidity	
	Complication rate	
	Positive surgical margin	
	Continence	

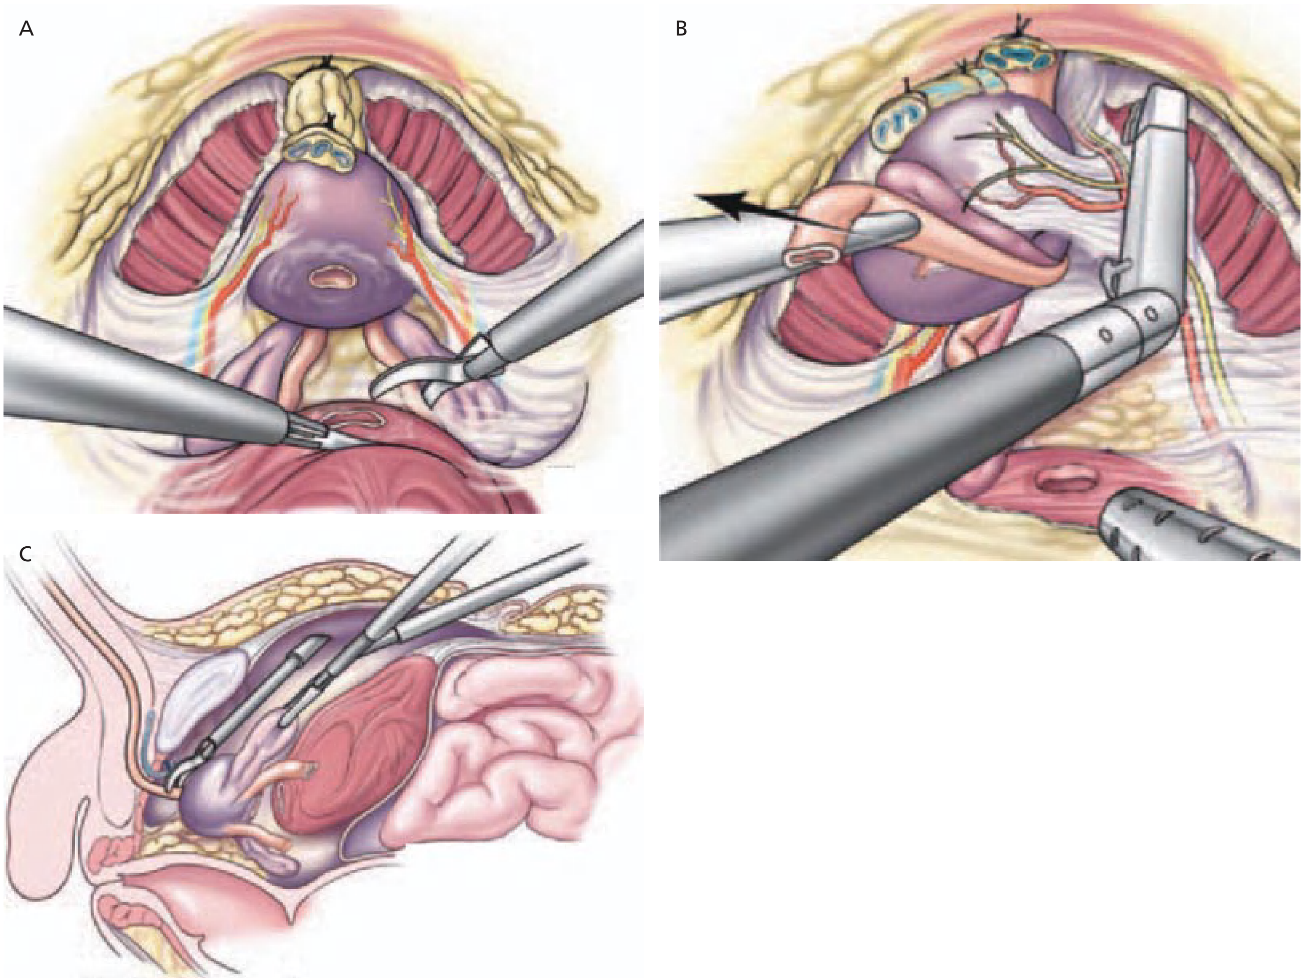

Figure 90.5 Antegrade technique of laparoscopic radical prostatectomy according to Ukimura *et al.* [22]. (A) Opening of the bladder neck and dissection of the vas deferens and seminal vesicles. (B) Dissection of the posterior surface and control of prostatic pedicles using the vas deferens as a retractor. (C) Division of the urethra. (Reproduced from Ukimura *et al.* [22], with permission.)

Recently, Takenaka *et al.* introduced the strategy of preservation of the puboprostatic collar [44]. We have added the preservation of the levator fascia to this strategy, yielding excellent short-term continence results.

Heilbronn technique for early continence (see Videos 90.1 and 90.2)

Conventional technique

Following lateral incision of the endopelvic fascia, the levator fascia is perforated, creating a dissection plane along the levator ani muscle (Figure 90.7). The levator ("periprostatic") fascia is incised secondarily to perform an interfascial nerve-sparing technique. This approach also includes division of both puboprostatic ligaments and distal ligation of the DVC (Figure 90.8).

New technique

Following medial incision of the endopelvic fascia below the puboprostatic ligaments, the avascular plane between the levator and prostatic fascia is developed (Figure 90.7). Thus, the intrapelvic branch of the pudendal nerve remains covered by levator fascia. The DVC is sutured over the mid part of the prostate to preserve the puboprostatic collar. For division of the DVC a 120° endodissector is placed over the prostatovesical junction (Figure 90.8), rotating the prostate towards the urethra, and the anterior striated sphincteric complex is reached [45]. The urethra is transected just distal to the veru montanum, preserving the rectourethralis muscle. Whenever indicated, we perform a bladder neck-sparing technique. After dividing the bladder neck, the prostatovesicle muscle is incised close to the prostate to be used for posterior reconstruction of the anastomosis.

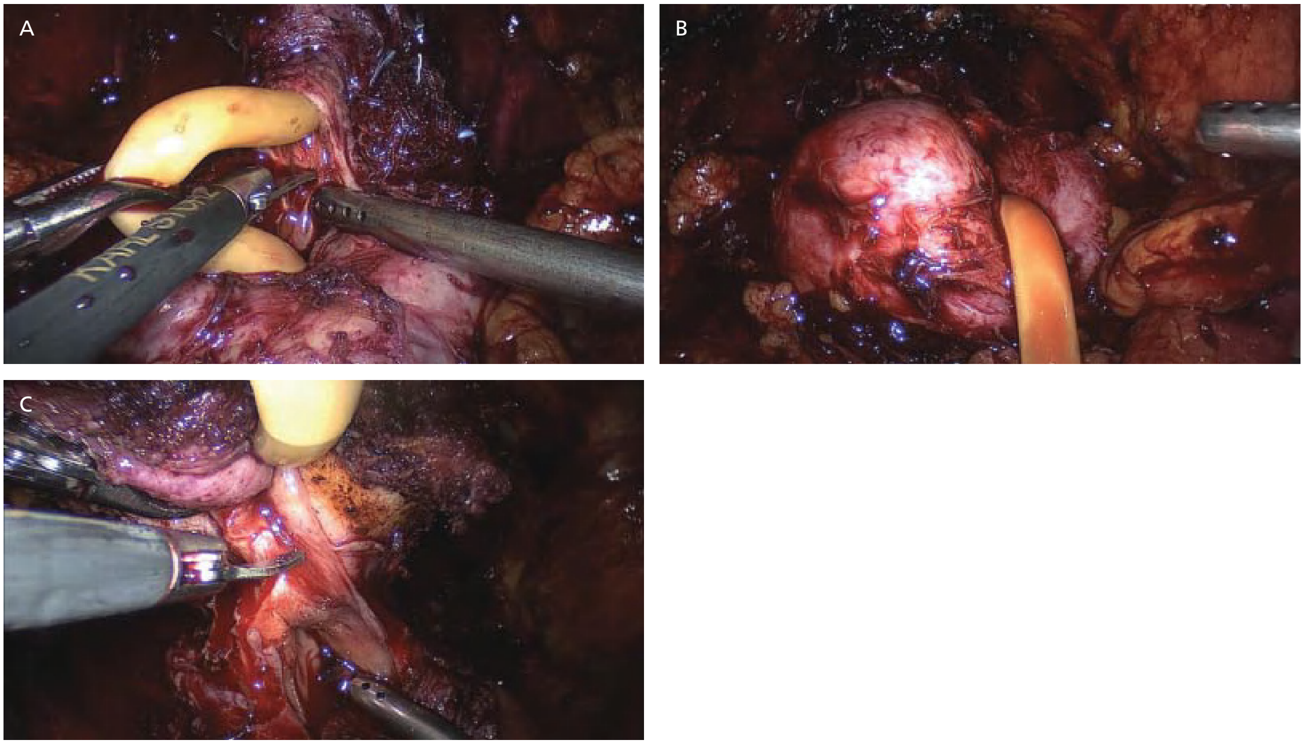

Figure 90.6 Retrograde technique of laparoscopic radical prostatectomy (Heilbronn technique). (A) Division of the urethra. (B) Posterior dissection using the Foley catheter as a retractor. (C) Bladder neck incision using the loop of the catheter as a retractor.

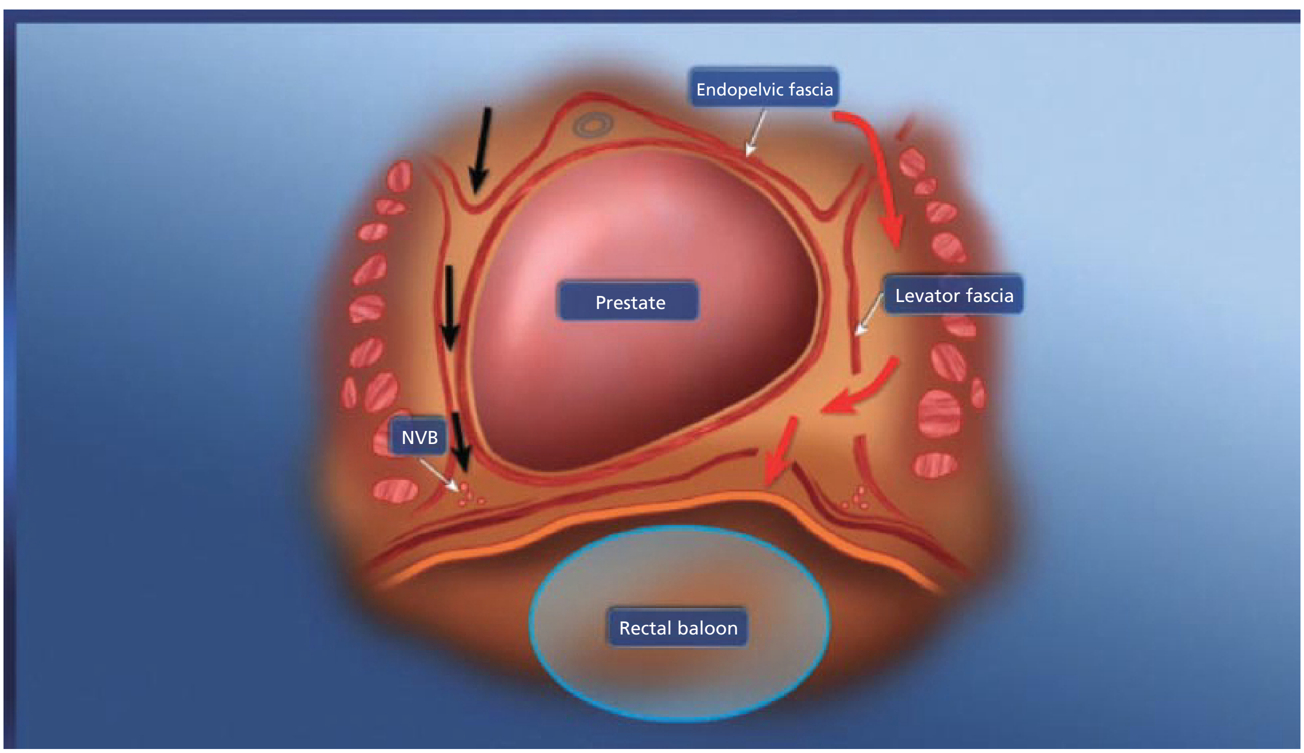

Figure 90.7 Incision of the endopelvic fascia. Red arrows: without preservation of the levator ani fascia (conventional technique). Black arrows: with preservation of the levator ani fascia. NVB, neurovascular bundle.

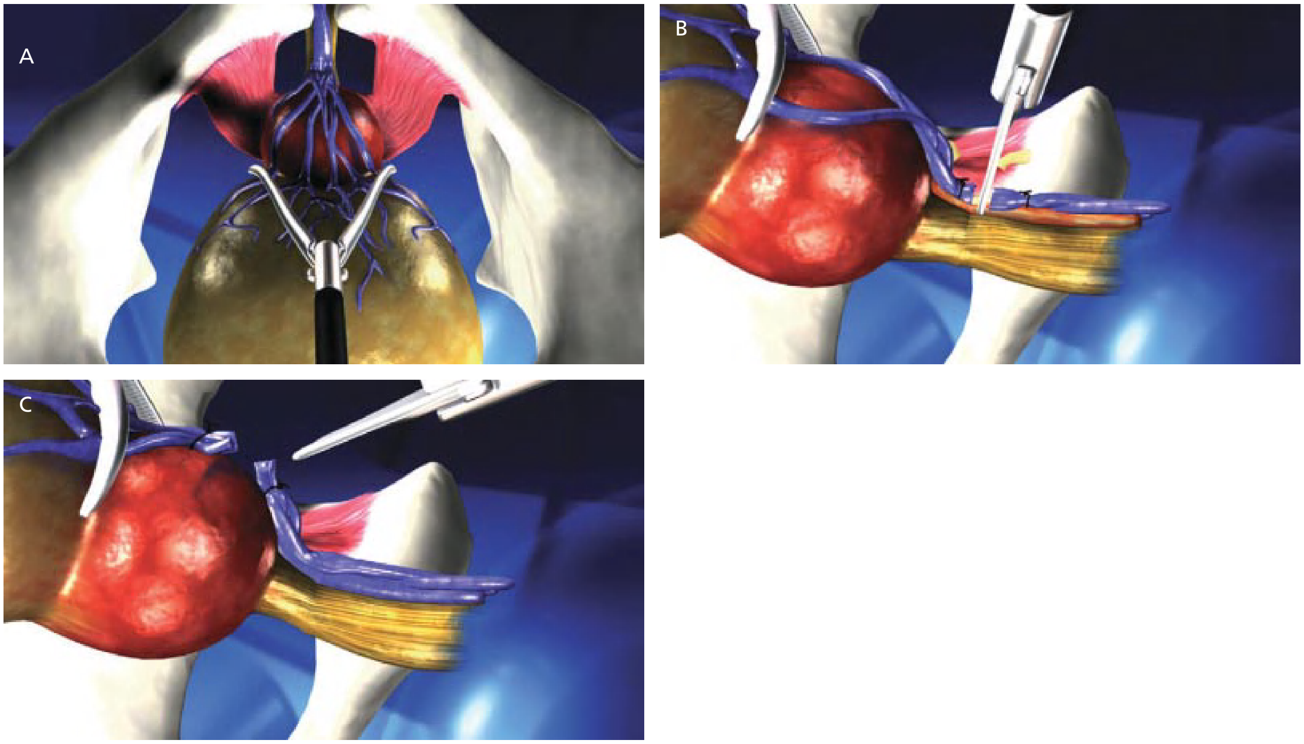

Figure 90.8 Division of the dorsal vein complex (DVC). (A) A 120° endodissector is placed over the prostatovesical junction. (B) Conventional technique: distal suturing and division of the DVC. (C) New technique: division of the DVC at the mid prostate.

Non-nerve-sparing technique

If nerve sparing is contraindicated, the NVBs are clipped distal to the urethra using 10-mm titanium clips. No Hem-o-lok clips are used to avoid migration into the anastomosis. The proximal pedicles are clipped pararectally to minimize the risk of positive margins.

Nerve-sparing techniques

Preservation of the NVBs can be performed using an antegrade or retrograde technique.

Antegrade technique

Antegrade dissection starts with the division of the proximal pedicle and release of the NVBs at the base of the prostate [8]. Finally, the bundles can be separated bluntly from the apex. The NVBs cannot easily be visualized without initially incising the levator fascia and developing the lateral NVB groove [46]. Gill *et al.* proposed intraoperative transrectal ultrasound monitoring to identify the course of the NVB [47]. Interfascial NVB dissection uses the prostatic fascia as a visible landmark, starting with its separation lateromedially [27, 42].

Retrograde technique (see Video 90.3)

Retrograde dissection reproduces the open technique with earlier release of NVBs [27, 42, 48–50]. The space between the urethra and the NVBs is dissected bluntly until Denonvilliers' fascia can be identified. The rectal balloon is inflated with 40–60 mL of air. The prostatic fascia is incised and small branches to the NVBs are controlled with 5-mm titanium clips (Figure 90.9A). The same is achieved during posterior dissection after incision of the urethra. Following division of the bladder neck, the course of the NVBs is identified to determine the clip position to control the proximal pedicle (Figure 90.9B).

Antegrade versus retrograde nerve sparing (Table 90.3)

All steps can be performed using either technique, and neither should be regarded as a pure technique [48]. Commonality exists with regards to accomplishing an interfascial dissection and early visualization of the NVBs, use of task-specific instrumentation such as fine right-angled and curved dissectors, and avoiding thermal energy during steps relevant to NVB preservation [51, 52].

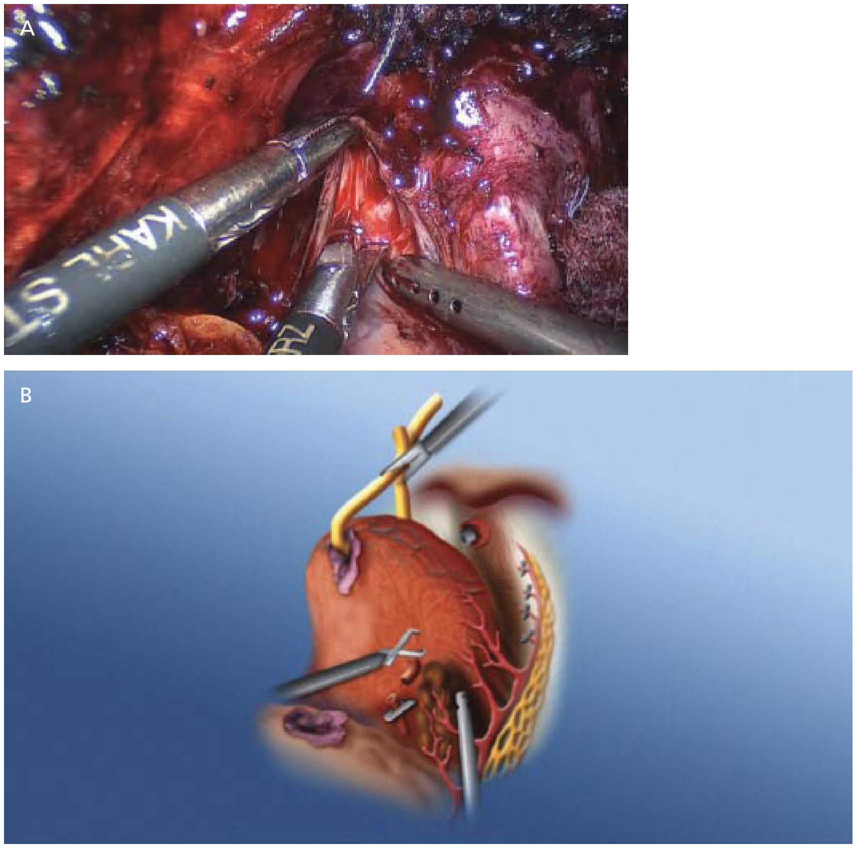

Figure 90.9 Retrograde nerve-sparing technique. (A) Early release of the neurovascular bundles at the apex using 5-mm titanium clips. (B) Controlled division of the proximal pedicle.

Table 90.3 Advantages and disadvantages of retrograde versus antegrade neurovascular bundle preservation during laparoscopic radical prostatectomy.

Technique	Advantages	Disadvantages
Retrograde	Earlier identification of neurovascular bundles (NVBs) (i.e. hemostasis at dorsal vein plexus)	Technical difficulty
	Exposure of NVBs during every step	Late control of proximal pedicle
	Direct transfer of existing techniques of open radical prostatectomy	
Antegrade	Early control of prostatic pedicle, resulting in minimal bleeding	Later identification of NVBs still covered by levator fascia
	Early control of seminal vesicle arteries	Suboptimal exposure of prostatic base during control of prostatic pedicles
	Better working angle for the instruments	
	Dissection proceeds along surgeon's natural line of site	

Compensated for by early incision of the endopelvic fascia.

Entrapment of the specimen

The specimen is entrapped in the self-opening extraction bag (Karl Storz, Tuttlingen, Germany) by pulling the purse-string out onto the skin surface via the left 10-mm port. Thereafter, the port is reinserted parallel to the bag.

Urethrovesical anastomosis

For the urethrovesical anastomosis, the right medial port and left lateral port are used to provide an optimal angle (25–35°) between the instruments (Figure 90.10A). The anastomosis can be accomplished by the interrupted, continuous, or single-knot technique [53].

Posterior reconstruction

Rocco and Rocco reported significant improvement of early continence following adaptation of the prostatovesicle muscle to the rectourethralis muscle [54] (Figure 90.10A–C). However, Menon *et al.* did not find any advantage over a single-knot technique alone [55]. Using our old technique of dissection lateral to the levator fascia, the Rocco suture did not improve early continence. However, it did release tension on the anastomosis as well as the NVBs.

Van Velthoven single-knot technique (see Video 90.4)

Anastomosis is performed using two bi-colored sutures (17-cm PDS 3/0 and Biosyn; RB1-needle) knotted together. We start at the 6 o'clock position on the bladder neck and then take the posterior urethra. Once the posterior part of the anastomosis is accomplished, the sutures are pulled to adapt the bladder neck and urethra (winch mechanism) (Figure 90.10D–F). An 18F catheter is inserted and the anastomosis is completed. In difficult situations, a special bougie allows insertion of a guidewire for safe placement of the catheter.

Reconstruction of the bladder neck

Posterior bladder neck reconstruction is necessary when the orifices are close (<5 mm) to the resection line (i.e. in cases of a large mid lobe). Anterior reconstruction may become necessary when bladder neck preservation is not possible or indicated.

Retrieval of the specimen

After placing the drainage tube via the right medial 10-mm port, the bag is extracted via the periumbilical incision.

Results

A systematic literature search using the terms "laparoscopic radical prostatectomy", "ergonomics", "comparative studies", "robot-assisted radical prostatectomy" (RALP), was performed in Medline, Embase and Pubmed. Inclusion criteria were randomized controlled trials (RCT) or observational series and reviews of good quality. Primary outcome parameters focused on the impact of ergonomics on performance and learning curve of the different techniques. Secondary outcome parameters were functional and oncologic outcomes after radical prostatectomy. In Heilbronn, we have performed 2200 LRPs since March 1999, including 200 with the da Vinci system [56, 57].

Twenty-seven comparative studies were identified [3]: 23 compared LRP with RRP; and four compared LRP with RALP: one randomized controlled trial [58]; nine nonrandomized prospective studies [32, 41, 59–65]; seven retrospective studies compared to contemporary series [66–72]; and five retrospective studies using historical series as controls [56, 73–76]. There are robust long-term data from major centers as well as from recent meta-analyses.

Perioperative data

Comparison of early laparoscopic series to relevant contemporary series of RRP [12, 33, 43, 77, 78] includes a major bias related to the different levels of surgical experience. Based on today's training programs, about 50 cases are necessary to learn LRP [7, 36, 79].

Operating times

Increased operating times (180–330 min) represent one of the criticisms against LRP (compared to RRP, 105–197 min; Table 90.4A) [80]. However, Frede *et al.* showed a decrease in operative time from 332 min for the first 50 cases to 196 min for the last 50 cases after 1000 procedure [34]. With experience, there was also a significant decrease in operating time with the extraperitoneal approach [36, 81].

Blood loss and transfusion rates

Compared to RRP, LRP demonstrated a significantly lower blood loss (189–1100 mL vs 550–1550 mL) and transfusion rate in cumulative analysis (Table 90.4B) [41, 55, 58, 60, 66, 68, 73, 82, 83]. In one study comparing 1134 LRP versus 3458 RRP cases, the transfusion rate was 4% versus 55% [84]. Also, the study by Hu revealed a 20% transfusion rate for RRP versus 4% for minimally invasive techniques [85].

(E) Bladder neck stitch (outside–inside) at 4 o'clock. (F) Adaptation of the posterior part of the anastomosis using the winch principle.

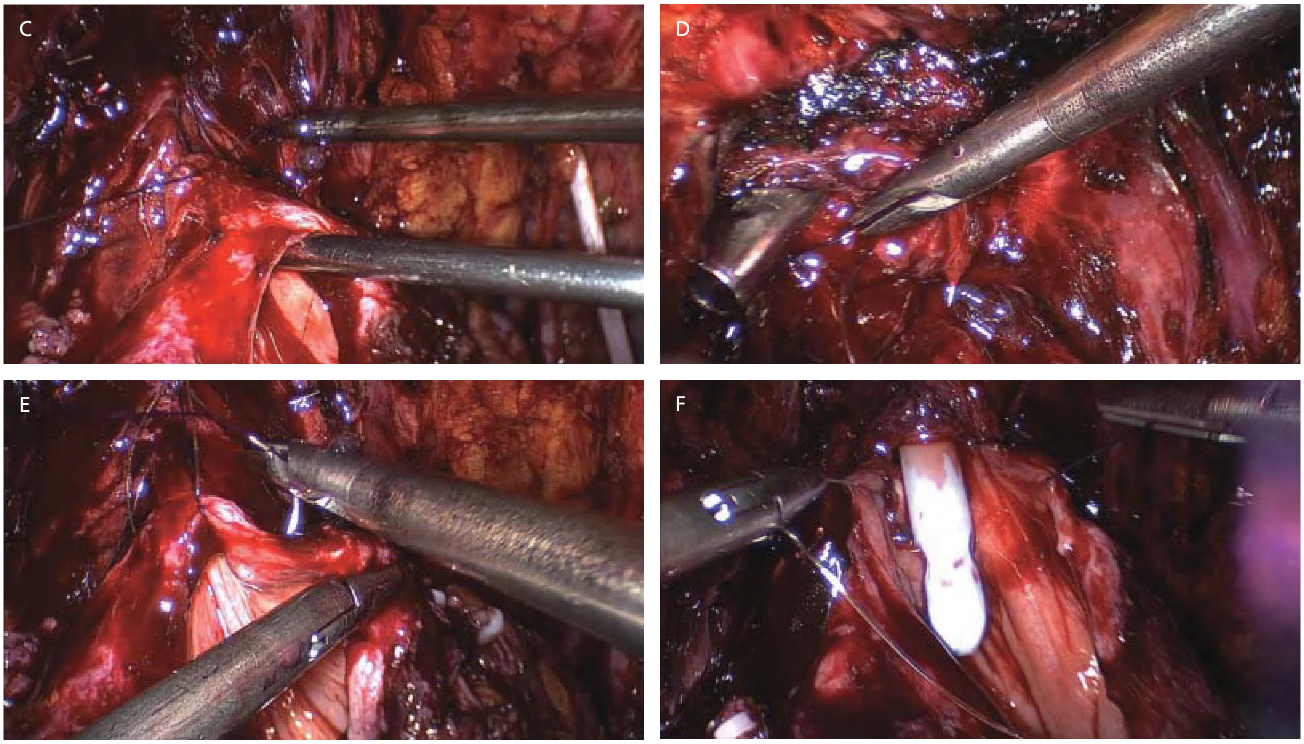

Figure 90.10 *Continued*

Postoperative pain

Most of the studies used a visual analog scale or the morphine equivalent requirement [41, 56, 58, 59, 64, 69, 70]. Pain scores were slightly lower during postoperative day 1 in patients undergoing LRP [58]. There was no statistically significant difference in the required morphine sulfate equivalent. The level of postoperative pain might be affected by epidural infusion of analgesic following RRP [86].

Catheter times and hospital stay

Overall, catheterization times ranged between 6 and 14 days after LRP and 5 and 22 days after RRP [56, 58, 59, 70, 74]. The catheter was withdrawn early in a higher percentage of LRP patients compared to RRP. Length of stay in hospital was significantly shorter for LRP patients [41, 56, 59, 65, 70, 74, 78]. However, there was a wide variation in length of stay due to the differences in economic health systems and cultural background.

Complications

We classified complications according to the modified Clavien system [86] (Table 90.5). In a study with follow-up of 37 months, Rabbani *et al.* reported 19.9% Clavien 1–2 complications following RRP compared to 37.3% after LRP [87]. However, they listed transfusion rates of 55% after RRP and 4% after LRP separately. Therefore, many patients receiving transfusions were not registered as Clavien 2. Novara *et al.* observed 19% Clavien 1–2 (including 5.3% transfusions), similar to the rates in our series (21.7% including 10.4% transfusions) [3, 88]. In Rabbani *et al.*'s series, Clavien 3–5 complications occurred in 6.4% after RRP and 8.9% after LRP, compared to 11.4% in our series (Table 90.5).

The low conversion rates (1.9–2.2%) in all major series reflect the careful introduction of LRP [20, 59]. In a recent multicenter study, technical reasons or unclear anatomy of the tumor were the reasons for conversion to open surgery [20]. A single retrospective study reported a lower rate of anastomotic strictures in LRP compared to RRP [56]. No differences were found between LRP and RALP.

Predictive factors for complications (Table 90.6)

Novara *et al.* identified prostate volume greater than 50 cm as an independent predictor of complications [88], but Zorn *et al.* did not find any impact of prostate volume for RALP [89]. Additionally operating time longer than 4 h, non-nerve sparing technique, and transperitoneal access predicted a higher rate of complications. However, there is a relationship between the institutional learning curve and these factors, with the number of cases performed by the being a predictive factor [88].

Table 90.4 Comparison of intraoperative outcome following laparoscopy (LRP) and retropubic radical prostatectomy (RRP) (meta-analysis according to Ficarra *et al.* [80]). (A) Operating times (min). (B) Transfusion rates.

Oncologic results

Positive margins

Comparative and cumulative studies have provided data on positive surgical margin (PSM) rates ranging from 11% to 37% after RRP, 11–30% after LRP, and 9.6–26% after RALP (Table 90.7). Accordingly, Guazzoni *et al.* demonstrated overlapping PSM rates [58]. No differences were found between LRP and RALP, considering early [90] and more advanced phases [91] of the RALP learning curves.

Prostate-specific antigen recurrence

There are only few long-term studies. Guillonneau *et al.* reported an overall actuarial biochemical progression-free survival rate of 90.5% at 3 years [92]. The rates were 92% for pT2a, 88% for pT2b, 77% for pT3a, and 44% for pT3b. Our data revealed overall 10-year PSA-recurrence-free survival of 65%, including 80% for pT2 and 51% for pT3–4 (Figure 90.11A). Compared to RRP, the oncologic outcome was similar (Table 90.8).

The multicenter study published by Vickers *et al.* analyzed the learning curve of LRP based on the PSA-recurrence-free status [117]. In an earlier RRP study, it was identified that 250 cases need to be performed by a surgeon to achieve a plateau. In the LRP series including more than 5000 patients, this plateau was reached after 750 patients. However, there was an ongoing improvement (Figure 90.12), indicating some advantages attributed to videoendoscopic surgery.

Survival data

Clinical progression-free 10-year-survival was 97% for pT2 and 81% for pT3 (Figure 90.11B). We observed a local recurrence in 3% of pT2 and 13% of pT3/4 cases managed mostly by early adjuvant irradiation. Overall, 10-year survival was 96.8% for pT2 and 92.2% for pT3 (Figure 90.11C) (unpublished data)].

Functional results

Evaluation of functional results after radical prostatectomy is difficult, because only a few comparative studies have used validated questionnaires [70].

Continence

To determine *early* continence, we introduced the urine loss ratio (ULR) based on a micturition protocol following catheter removal [118]. If ULR is below 0.05, the probability that the patient will be continent after 3 weeks is 89%. Using ULR, we compared our previous technique with and without posterior reconstruction and found no impact on ULR (52% vs 54%). When using

Table 90.5 (A) Complication rates in consecutive cases (n = 2200) of laparoscopic radical prostatectomy at a single center. (B) Comparison of complication rates of laparoscopic and retropubic prostatectomy in the literature.

RR, relative risk.

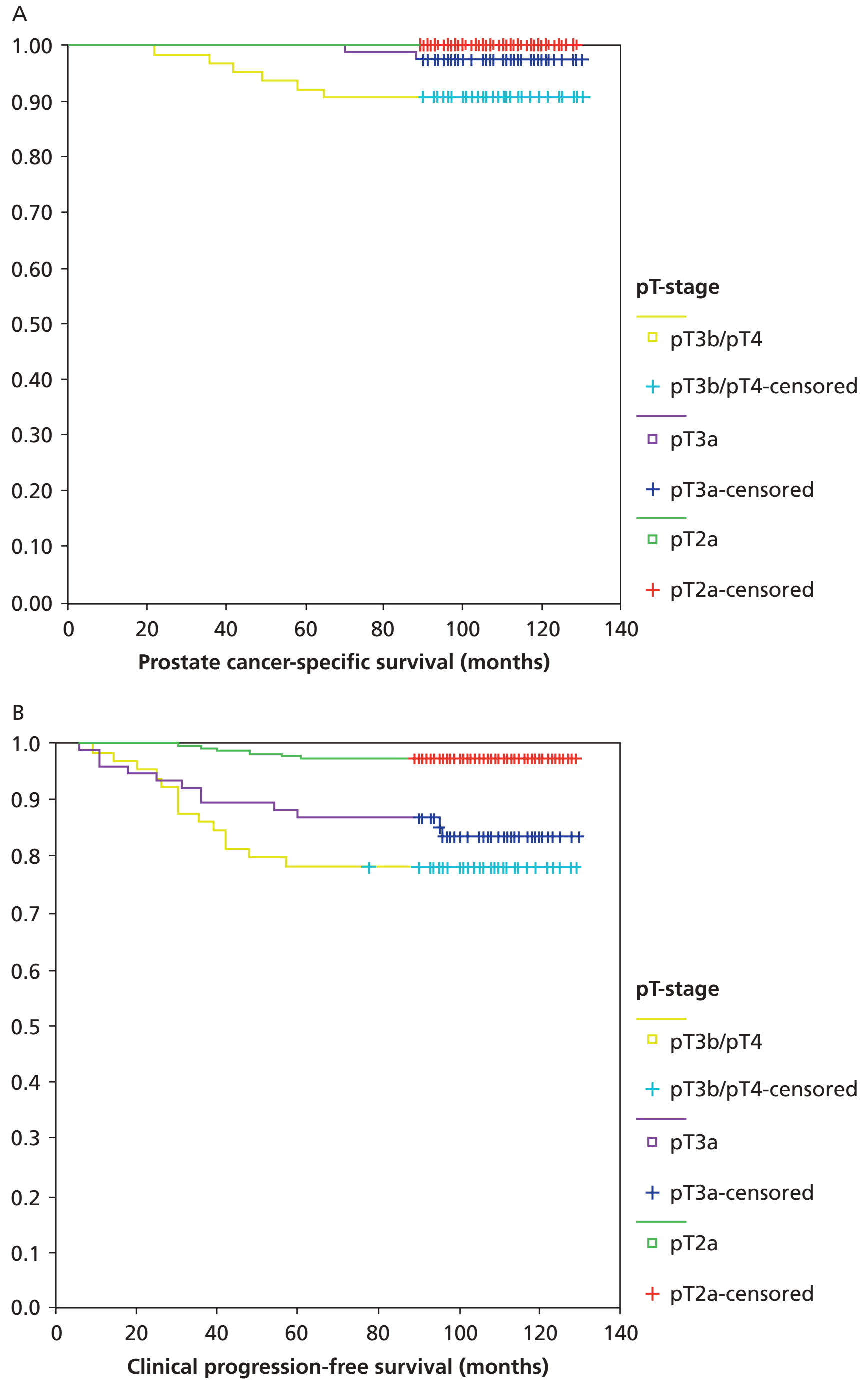

Figure 90.11 Oncologic outcome of laparoscopic radical prostatectomy at 10 years follow-up (Heilbronn experience). (A) Prostate-specific antigen (PSA) recurrence. (B) Clinical progression-free survival. (C) Overall survival.

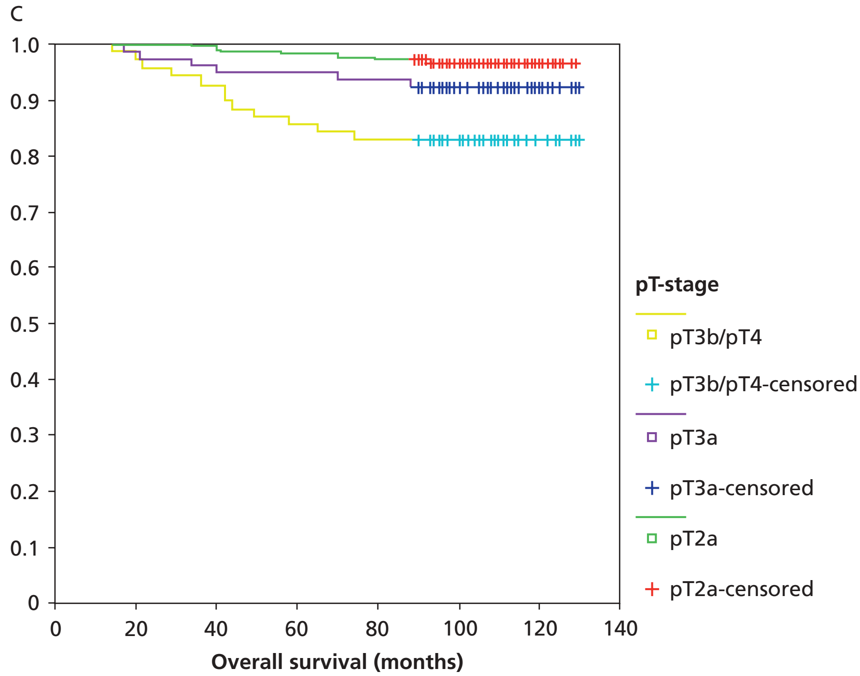

Figure 90.11 *Continued*

the Heilbronn approach, the rate of minimal urine loss increased to 92% (Table 90.9).

One comparative study has shown higher *long-term* continence rates in RRP patients [65]. When evaluating the learning curve of LRP, continence recovery was better with RRP [68]. Patients undergoing LRP had a two-fold higher risk of being incontinent [65]. In major series from referral centers, however, 12-month continence rates (66–95% vs 60–93%) overlapped for RRP and LRP (Table 90.10A). The only study comparing urinary continence after LRP and RALP failed to show any difference in 6-month rates (118) (Table 90.10B).

Erectile function

Two studies have used validated questionnaires such as the International Index of Erectile Function (IIEF) [61, 119]. Three studies have compared RRP and LRP [60, 61, 65] and none showed any advantage favoring LRP. A single retrospective study comparing historical series after LRP and RALP demonstrated a statistically insignificant trend in favor of RALP [119]. No comparative study showed any significant advantage for LRP at 12 months (42–76% vs 10–93%).

Cost-effectiveness

Three cost calculations from the USA are available (120–122). They suggested that LRP was more expensive than RRP (RRP US$5253–8596; LRP US$5058–10 414). However, with the use of nondisposable instruments, completing LRPs in 3.4 h, and discharging patients on postoperative day 2, cost equivalence between the two could be achieved [120]. Lotan *et al.* included RALP in their analysis and found a cost advantage of RRP of US$487 and US$1726 over LRP and RALP, respectively [122]. The shorter operative time (140 min vs 160 min) and length of stay (1.2 days vs 2.5 days) did not compensate for the added expense of RALP.

Perspectives on laparoscopic radical prostatectomy

Ergonomic deficiencies

During LRP, surgeons suffer from high levels of mental and physical stress. After 4–5 h, the fatigue syndrome sets in, characterized by mental exhaustion, and reduced dexterity and capacity for good judgment [123, 124]. Back pain is common [124]. The force required to control the laparoscopic instruments can be six times greater, and the problem is magnified further by the nonergonomic design of the handles [125]. Also, the assistant is in a high-risk ergonomic position, created by the left leg bearing 70–80% of body weight over time [126]. Even if the da Vinci system has optimized the ergonomics of laparoscopic surgery, it still has limitations and is not cost-effective. Therefore, a significant

effort needs to be invested to improve the ergonomics of laparoscopy.

Technical advances

The recent introduction of high-definition technology has significantly improved depth perception. In 1999, a special chair was proposed with pedal switches to improve the ergonomics [127]. Since 2005, we have used a surgical support during LRP to reduce the stress on the knee joints; however, during anastomosis the surgeon needs to stand up. Recently, a specially designed ergonomic body support consisting of a platform with foot pedal, a semi-standing support, a remote control, and a chest support was presented [128]. Electomyography results showed an average reduction of stress on the muscle of 44% for the erector spinae, 20% for the semi-tendinosus, and 74% for the gastrocnemious muscle when using the chest support. The average muscle reduction using the semi-standing support was 5%, 12%, and 50%, respectively. In 2010, first experiences were published for the use of a platform (Ethos), which allows the surgeon to sit over the patient's head. This may overcome all physical stress problems concerning rotation, unstable standing, and weight balance in the future.

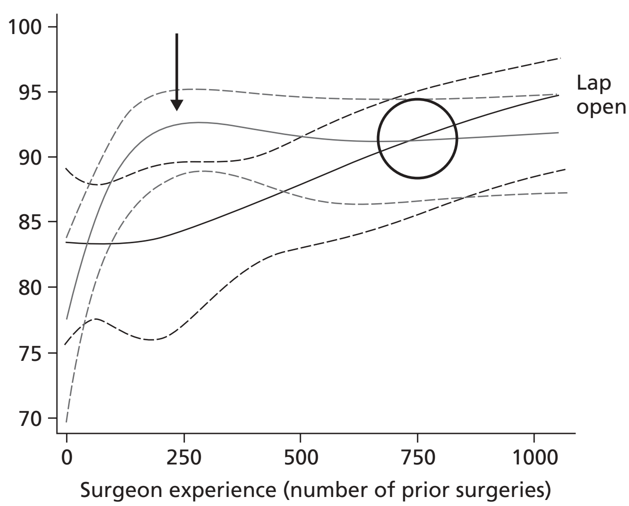

Figure 90.12 Comparison of learning curves of laparoscopic (LRP) and retropubic radical prostatectomy (RRP) (reproduced from Vickers *et al.* [117], with permission).

LESS radical prostatectomy

Laparoendoscopic single-site surgery (LESS) has received significant attention in general surgery, where transvaginal cholecystectomy is performed increasingly. There are also first reports of LESS radical prostatectomy using a periumbilical incision for port placement [129]. Interestingly, marketing plays also an important role in offering an "incisionless" removal of the gallbladder or prostate. The development of prebent and flexible instruments as well as steerable ports will significantly impact the ergonomics of this approach.

Conclusions

There is no doubt that LRP has lost the race against RALP in the USA. Nevertheless, LRP has proven to be safe and provides at least similar functional and oncologic outcomes to RRP. It will be interesting to see if future improvements, particularly concerning the ergonomics of the procedure, will impact on the role of LRP worldwide.

Table 90.9 Impact of posterior reconstruction versus preservation of puboprostatic collar and levator ani fascia on early continence based on the urine loss ratio (ULR) following catheter removal (same surgeon, <70 years, pT2/3, bilateral nerve sparing).

ULR*	No posterior reconstruction No preservation of puboprostatic collar	Posterior reconstruction No preservation of puboprostatic collar	Posterior reconstruction Preservation of puboprostatic collar

CHAPTER 91
Robot-Assisted Radical Prostatectomy

Jason Y. Lee, Douglas W. Skarecky & Thomas E. Ahlering
UC Irvine Medical Center, Department of Urology, University of California, Irvine, Orange, CA, USA

Introduction

The first successful laparoscopic nephrectomy was performed in June 1990 by Clayman *et al.*, and it not only revolutionized the management of renal tumors, but galvanized the minimally invasive surgery movement in urology [1]. Lead by some of the very same pioneers, the initial description of a transperitoneal laparoscopic radical prostatectomy (LRP) was reported in 1992 in abstract form at the annual meeting of the American Urological Association (AUA) [2]. This initial case series was published several years later [3]; however, due in large part to the difficult reconstruction of the vesicourethral anastomosis and the lack of demonstrable patient benefit, the authors did not recommend the routine adoption of this technique. In the very same journal issue, Raboy *et al.* published their initial experience with an extraperitoneal approach to LRP, but also concluded that, although encouraging, further evaluation and refinements were necessary [4].

Despite tepid support in North America, by the late 1990s, the technique had made its way to a handful of centers in Europe. In 1998 the group at the Institut Mutualiste Montsouris in Paris, led by Drs Vallencien and Guillonneau, reported their initial experience with LRP after having completed almost 30 cases using a new antegrade approach [5]. Based on their initial results, these authors felt that LRP could be reasonably performed by a well-trained team, with comparable oncologic outcomes and perhaps improved functional outcomes. Although groups led by Dr Abbou in France [6] and Dr Rassweiler in Germany [7] reported similar early experiences with LRP, with the exception of a few centers in the USA, the technique largely remained in Europe.

Technically challenging, ergonomically demanding, and of debatable benefit over the traditional open retropubic radical prostatectomy (RRP), LRP was neither accepted nor adopted for routine application by mainstream urology in North America. This was in part due to the fact that, while laparoscopy was quickly adopted and applied in Europe, there were few laparoscopic centers of excellence in the USA at that time. These laparoscopic experts in Europe were more readily able to overcome the learning curve of LRP and perform some of the more technically challenging aspects of LRP, such as the vesicourethral anastomosis, while experienced open but laparoscopically naïve surgeons in the USA had difficulty.

In 2001, several groups in Europe introduced the urologic community to the da Vinci Surgical System® (Intuitive Surgical, Sunnyvale, CA, USA) with their initial reports of robot-assisted laparoscopic radical prostatectomy (RARP) [8–10], a technology initially applied in the cardiac surgery field [9, 10]. The following year, the first report of a large series of RARPs performed in the USA was published by Menon *et al.* at the Vattikuti Urology Institute in Detroit, Michigan, USA [11].

Initially described as "telepresence surgery," the da Vinci robot provided surgeons with a more ergonomic surgical platform in addition to increased instrument

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

dexterity and precision, hand tremor filtration, and improved three-dimensional vision. Despite a lack of long-term oncologic data, and initially buoyed in part by a combination of patient demand and marketability, RARP has grown in a geometric fashion over the last decade. In 2007, it was estimated that over 60% of all radical prostatectomies performed in the USA were done using the da Vinci robotic platform. This represented a growth of approximately 50% over the previous year, when only about two of every five radical prostatectomies performed were done so using the RARP technique. Extrapolating from this trajectory, some have estimated that by 2010, nearly 80% of all radical prostatectomies performed in the USA will have been done so using the da Vinci robot [12].

The learning curve

The learning curve associated with RARP has been shown to be much more accommodating than that of LRP, if by nothing else but the simple fact that more urologists have successfully incorporated this technology into their practices than have LRP. Studies have demonstrated that proficiency in LRP can be achieved after 40–100 cases in the hands of experienced laparoscopic experts [13, 14]. However, the RARP learning curve may be as low as 10–20 cases, based on operative times, for even the laparoscopically naïve surgeon [15, 16]. It should be mentioned, however, that the learning curve for RARP, as with any new innovative surgical technique, is dichotomous in nature. The "technical" learning curve is significantly different from the "outcomes" learning curve, a concept that has been raised by those interested in seeing the safe and effective application of this technology [17]. Although a safe RARP may be performed efficiently (i.e. within an acceptable operative duration), the ability to effectively achieve oncologic and functional outcomes similar to those of open radical prostatectomy may take significantly longer. As Herrel and Smith have reported, the learning curve to reduce positive surgical margins to a level comparable to open radical prostatectomy may take upwards of 150–250 cases [18].Careful patient selection, however, can help reduce the slope of the early learning curve associated with the adoption of this procedure. Table 91.1 delineates some of the patient and disease factors that should be avoided during this early learning curve. The surgeon should be especially cognizant of the challenges of large prostates and obese patients. Large prostates, generally defined as greater than 50 cm^3 on ultrasound, are a challenge due to the confines of the bony pelvis. A caveat that should be considered is that transrectal ultrasound typically underestimates prostate weight by 20% [19]. For similar reasons, in an obese patient with a fatty bladder and/or rectosigmoid colon that restricts the working space, vision and ease of dissection can be dramatically impaired.

Table 91.1 Patient and disease features to avoid during initial learning curve.

Prior history of abdominal or inguinal surgery
Prior history of prostatitis, prostate surgery (e.g. transurethral resection or microwave thermotherapy of the prostate, etc) or prostate radiotherapy
Large prostates (>60 g)
Body mass index >30
Features suggestive of a narrow pelvis
Evidence of a large median lobe
High preoperative erectile function [e.g. five-item International Index of Erectile Function (IIEF-5) score >21]
Patients requiring pelvic lymphadenectomy

Perioperative care issues

In order to ensure both safety and efficiency in the operating room, patient positioning should be a process that involves every member of the surgical team. The anesthesiologist should be made aware of the steep Trendelenburg positioning that will be required and some of the nuances of maintaining a patient in this position for long periods of time.

The nursing team should be able to facilitate the swift and safe preparation and docking of the patient cart. A detailed description of patient preparation and operating room set-up is provided in Chapter 68 (Figure 91.1).

The patient is initially placed in the supine position, with arms tucked and padded at their side. The use of shoulder rests should be avoided as this can lead to serious brachial plexus injury. The legs can either be placed on spreader bars and gently separated or placed in padded boot stirrups in a low lithotomy position. The primary complication to avoid is hyperextension of the femoral nerve when using spreader bars and careful padding of the posterior knee to prevent nerve impingement when using stirrups. The legs are lowered slightly to facilitate docking of the robot and after placing the patient in steep Trendelenburg, a Mayo stand should be placed over the patient's head and shoulders without interfering with the anesthesiologist's access to the endotracheal tube. This serves to protect the patient's face from the instruments and camera when they are being changed or cleaned, as well as to provide a place to rest the assistant's arm. A 16 or 18F Foley catheter is inserted after the sterile drapes have been placed. It has been demonstrated that catheters of 22F or greater can

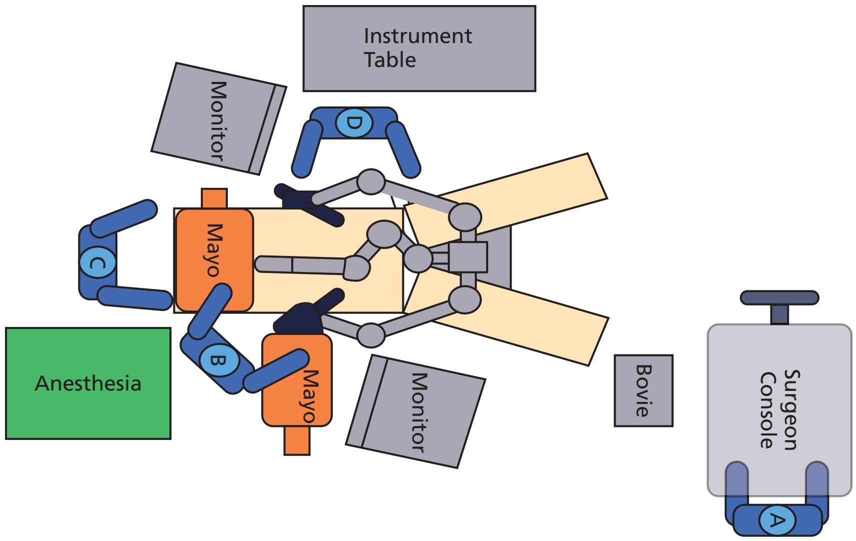

Figure 91.1 Operating room set-up for robot-assisted radical prostatectomy.

be associated with nearly a 10% risk of fossa navicularis strictures [20].

Corneal abrasions, although infrequent, are considered to occur secondary to positional eye edema. When patients awaken, the edema irritates the eyes and they inadvertently rub and scratch their eyes, resulting in corneal abrasion. Foam-based safety goggles should be placed over the patient's eyes for about 90 min in the recovery room, until the patient is fully alert and oriented enough not to rub their eyes.

A multimodal approach to postoperative pain management is employed with avoidance of narcotics as much as possible. Unless otherwise contraindicated, patients are started on ketorolac as the wounds are being sutured, but always prior to extubation. We aim to have the patient pain free when they awaken in the postanesthesia recovery room. Patients are discharged from the hospital on postoperative day (POD) 1 and have prescriptions for ibuprofen and acetaminophen if needed. We find that about 80% of patients are off pain medications by POD 4. We avoid narcotics because although they may control pain well, the resulting constipation leads to prolonged bloating and prolonged need for pain medication.

Thigh-high external pneumatic compression devices are used both during surgery and in the postoperative period as part of routine antithromboembolic care. Early ambulation protocols beginning the evening of surgery are also implemented; we ask patients to walk as much as one half mile on POD 1. Using this protocol we have not seen either deep vein thrombosis or pulmonary embolism in more than 750 consecutive patients.

As a rule, urethral catheters are routinely removed on POD 7 without cystography, except for those rare cases when patients continue to experience hematuria or a complicated bladder neck reconstruction was required.

Pneumoperitoneum and trocar placement

A detailed description of the basic principles of gaining access into the peritoneum, establishing pneumoperitoneum, and trocar placement are outlined in Chapters 70, 74, and 75. As such, only a brief discussion of the finer points of trocar placement specifically for RARP follows.

The recommended distance between all robotic trocar sites is approximately 10 cm. This allows for maximal range of motion with minimum clashing of robotic arms. With the standard da Vinci robot, the arms have a maximum working length of 25 cm. As demonstrated by Pick *et al.*, instrument ports should thus be placed no further than 18 cm from the pubic symphysis to ensure the arms can reach the necessary depth of the working field [21]. With the newer da Vinci S and Si robots, this limitation on working length is no longer a significant issue.

With the newer four-arm robotic systems, six ports are placed for the procedure: one camera port, three robotic ports, and two assistant ports (Figure 91.2). The camera is usually placed above the umbilicus through a 12-mm port inserted using a blunt-tipped trocar, although other descriptions have the port placed lateral to or below the umbilicus. A transverse curvilinear incision at the perimeter of the umbilical crease is employed as this provides for better cosmesis at the skin level and a stronger fascial closure. Recent analysis of outcomes data from our institution has demonstrated the physical

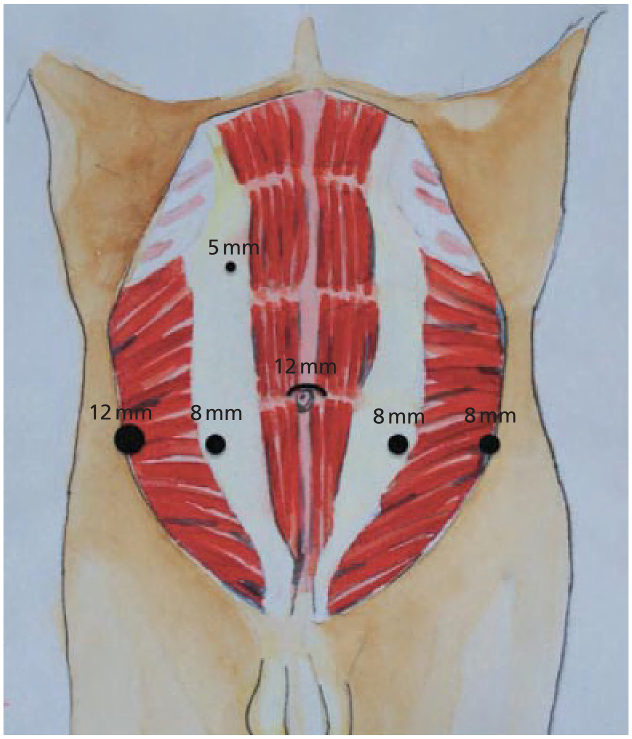

Figure 91.2 Port placement for robot-assisted radical prostatectomy

benefits of this transverse incision, as opposed to the traditional vertical midline incision [22].

The other ports are placed, as outlined in Figure 91.2, under direct vision. The robotic fourth arm port can be placed on either the patient's right or left side, which is mainly dictated by surgeon preference and the surgical assistant's hand dominance. For left-hand dominant assistants, it is preferable to have the assistant sit at the patient's right and as such, this port should be placed on the patient's left side. For right-hand dominant assistants, it is preferable to have them sit on the patient's left side with the robotic fourth arm port on the patient's right.

Several different instrument combinations have been described for use during RARP and choice is mainly based on surgeon training and preference. Most surgeons will use a long-tipped or ProGrasp™ forceps for the fourth arm and a bipolar Maryland or PK™ dissecting forceps for the left arm. As for the right arm, while some prefer to use a monopolar hook or monopolar flat spatula, we prefer a pair of monopolar scissors.

Operative technical steps

General approach

The majority of RARP surgeons utilize a transperitoneal approach, although some have advocated an extraperitoneal approach [23–25], citing decreased risks of bowel injury and postoperative ileus as some of the advantages [23, 26]. In addition, institutional differences exist as to whether to take an anterior approach [17, 27, 28] or a posterior approach to the seminal vesicles, as described initially by the group from Montsouris [13]. Others have also debated the differences between an ascending, retrograde dissection versus a descending, antegrade dissection [8, 11, 14, 29], or even some combination of the two as is performed in open RRP [9, 30].

Understanding that surgeon preference is likely the most significant factor in determining which approach is employed, we prefer a transperitoneal, anterior approach with antegrade dissection. This approach allows for optimal visualization during dissection of the neurovascular bundles (NVBs). Using the principle of triangulation, dissection in the caudal direction provides for better visualization of the structures being dissected, as compared to trying to see around the bulky prostate and dissecting back towards the bladder. It also allows the surgeon to perform the often difficult apical dissection after mobility of the prostate has been established. Finally, the antegrade approach also allows the surgeon to better identify and preserve the NVBs, owing to the fact that the vascular pedicles to the prostate are a consistent landmark that aid in the reliable identification of the interfascial plane between the prostatic capsule and NVB.

Anterior bladder mobilization and retraction suture

After successful placement of all trocars and confirmation that all instruments are in working order, using a 0° laparoscope, an inverted "U"-shaped incision is made in the anterior peritoneum from one inguinal ring to the other, with the base of the "U" placed close to the umbilicus across both medial umbilical ligaments. The arms of the "U"-shaped incision should be carried down to the inguinal ring until the crossing vas deferens is identified, thus allowing for adequate mobilization of this bladder-containing "flap." Through a combination of blunt dissection and electrocautery, the space of Retzius is entered and the bladder is "dropped" from the anterior abdominal wall, exposing the pelvic side wall and the posterior aspects of the pubic symphysis and pubic crest. Care should be taken not to traumatize the pelvic bone as this can result in meddlesome bleeding that can often be difficult to control.

Once the bladder is fully mobilized, we recommend a full-length 3-0 monocryl retraction suture be placed at the top of the urachus and be brought out through the 5-mm assistant port found in the right upper quadrant of the abdomen. This cephalad retraction suture takes 2–3 min to place and pulls the bladder and rectosigmoid

colon out of the pelvis, significantly improving exposure and working space, thereby freeing the fourth arm or assistant. It also serves to protect both the large and small bowel from inadvertent upstream thermal injury as the bladder "flap" separates all instruments from the bowel (see Video 91.1).

The fatty tissue overlying the prostate is removed in order to improve visualization of the puboprostatic ligaments, dorsal vein, and anterior bladder neck. Although not routinely performed at all institutions, we believe that this maneuver facilitates the apical dissection and reduces the risk of anterior apical positive margins. This will be discussed in further detail later in the chapter. Invariably, the superficial branch of the dorsal venous complex (DVC) is encountered during this step and is cauterized and divided. After the fatty tissue is dissected off the prostate, it is further dissected off the bladder and then submitted for pathologic examination. Technically, there is no reason to leave the fatty tissue attached to the bladder and removing it gives better visualization of the anterior bladder neck. Furthermore, the lateral limits of this fatty tissue are in direct anatomic continuation with region 3 of an extended pelvic lymph node dissection. As reported by Finley *et al.*, this anterior prostatic fat contains lymph nodes in up to 15% of cases, resulting in potential pathologic upstaging in 2–3% [31] (see Video 91.2).

Control of dorsal venous complex and apical dissection

After the endopelvic fascia is incised with cold scissors, the prostate is mobilized laterally down to the membranous urethra, sweeping the levator muscle fibers off the prostate with little to no cautery used. Care must be taken not to avulse the occasional perforating vessels, particularly closer to the apex, where they are more commonly found. Owing to the improved visualization of the da Vinci robot, the surgeon is then able to safely divide the puboprostatic ligaments and sweep away the overlying levator fibers found adherent to the DVC without encountering problematic bleeding. This detailed dissection is made possible by the 12x magnification of the working field and the removal of all anterior prostatic fat as described earlier, ultimately allowing for an increased length of DVC to be exposed. Subsequently a more distal ligation of the DVC is possible, facilitating a more precise dissection of the prostatic apex. Borin *et al.* demonstrated that dissecting and transecting the urethra an extra 3–6 mm distally resulted in no significant change in time to continence or overall continence rates, while decreasing apical positive surgical margin rates from 13% to 5.5% [32]. It is important to note that positive apical margins occur because of transection too close to the apical prostate.

Once adequate exposure has been obtained, it is our preference to use a 45-mm endoscopic stapler with a vascular staple load to ligate and divide the DVC. After the stapler has been engaged around the DVC, it is essential to maintain clamping for 60 s prior to firing the stapler. This ensures a more secure staple line by compressing all edema and vascularity out of the tissues. As described in the original publications of RARP, suture ligation remains the most popular method of controlling the DVC [10, 11, 27, 28]. However, we prefer the consistent and reproducible effect of stapling as it reliably gives a visual landmark to transect the urethra, hence reducing positive apical surgical margins (see Video 91.3).

Bladder neck transection

This is the most common part of the procedure with which inexperienced surgeons struggle. There are a number of reasons for this, but most prominent we believe is the absence of obvious visual landmarks, the innate natural anatomic variability of the junction, and the need to "feel" the difference between the prostate and the muscle of the bladder. After the camera is switched to the 30° down scope, we first identify the posterolateral contour of the prostate. Next it helps to see or "feel" the prostatovesical junction by compressing or pinching the bladder at its junction with the prostate. The prostate will result in minimal excursion of tissue, while compression of the bladder wall will be evidenced by an obvious mobility in the tissue. In and out traction on the Foley balloon also aids in identifying the anterior bladder neck.

Using the principles of traction and counter-traction to aid in defining the detrusor muscle fibers, electrocautery is used to divide the abundance of arteries and veins that traverse this region. However, muscle in and of itself will not bleed and can be cut "cold." We prefer to fully transect the anterior and posterior bladder neck muscle with scissors, reserving monopolar cautery (set at 25–35 W) for when vessels are encountered. Once the anterior bladder is opened down to the urethra in the midline, the Foley catheter is identified and deflated. The catheter tip is delivered into the surgical field and the robotic fourth arm grasps the Foley through its eyelet and pulls it anteriorly towards the abdominal wall. Counter-traction is provided by clamping the outer portion of the Foley catheter to the surgical drapes. This provides anterior retraction of the prostate off the posterior lying structures and also serves to prevent CO_2 leakage through the catheter. The bladder neck is then dismembered from the prostate using a bladder neck-sparing technique; however, it is important to open the bladder neck adequately to visualize the trigone and assist in defining the angle of transection of the posterior bladder neck. Sometimes the bladder attaches with a

gentle slope and at other times the trigone may approach the prostate at a 90° angle. The posterior bladder neck can be divided directly, trying to avoid inadvertent entry into the posterior prostate. It is our preference to approach the bladder neck laterally, entering the space between the posterior bladder wall and the seminal vesicles. The dissection starts laterally where some of the anterior vascular pedicle is still present. With cautery the vessels are transected. Again, the muscle is cut cold, which allows the dissection to proceed behind the posterior bladder neck into the space anterior to the vasa and seminal vesicles. As in open surgery, the surgeon must always be mindful of dissecting into the ureteral orifices proximally and the prostate gland distally.

Posterior dissection

As mentioned earlier, the Montsouris technique involves initial dissection through the pouch of Douglas to dissect the seminal vesicles off the rectum posteriorly and the bladder anteriorly. This dissection can be carried through Denonvilliers' fascia down to the apex of the prostate. If this approach has been taken, the transection of the posterior bladder neck will lead directly into this previously dissected plane. A theoretical disadvantage to this approach is that all sympathetic nerves coursing from the hypogastric autonomic plexus, between the lateral tips of the seminal vesicles and the bladder neck, are divided. As experience would dictate from retroperitoneal lymph node dissections for testis cancer, there is substantial innervation of the bladder neck in this area. All testis cancer surgeons are aware of the complication of retrograde ejaculation due to an incompetent bladder neck, which occurs when these nerves are resected.

As we do not perform a posterior dissection at the onset of the procedure, this step is completed after the bladder neck has been fully transected. Posteriorly, the anterior layer of Denonvilliers' fascia is identified and incised transversely to gain access to the ampulla of the vas deferens and the seminal vesicles. Initially, the right or left vasa and seminal vesicles are identified and dissected fully as a unit completely down to the tip of the seminal vesicle. We recommend simple transection of the vas without a locking clip as the clip is not necessary and can migrate into the anastomosis and has been implicated in severe bladder neck contractures. With one vas deferens and seminal vesicle dissected, the robotic fourth arm or surgical assistant uses these structures to provide further anterior traction on the prostate. This facilitates an easier dissection of the vas deferens and seminal vesicle on the contralateral side.

Once the vas deferens and seminal vesicles have been dissected bilaterally, using the robotic fourth arm or the surgical assistant, they are grasped *en bloc* and pulled anteriorly, exposing the posterior aspect of the prostate. After entering the posterior leaf of Denonvilliers' fascia in the midline, and exposing the perirectal fat, the rectum is mobilized off the prostate using a combination of sharp and blunt dissection. This dissection is carried out to the level of the prostatic apex, staying close to the posterior surface of the prostate. It is crucial to carry this dissection far enough distally to completely mobilize the rectum off the prostatic apex, and thereby reduce the chance of rectal injury during the apical dissection and transection of the urethra. Posterior counter-traction of the rectum provided by the surgical assistant facilitates this dissection.

Release of the neurovascular bundles

With the posterior dissection complete, the lateral prostatic vascular pedicles are well exposed as pillar-like structures. There have been several different techniques used to secure vascular control of the pedicles; however, all will agree that a minimal thermal technique is essential in preventing local thermal injury to the nearby NVB. Authors have described the use of locking hemostatic clips [33] or bulldog clamps [34, 35]. We have modified our initial technique using bulldog clamps and now employ lasso-style suture ligation of the vascular pedicles (Figure 91.3). This avoids the need to develop windows in the pedicle for placement of clips, which can often lead to bleeding, as well as the need for an experienced assistant who can place and remove clamps accurately and efficiently (see Video 91.4). Regardless of the technique employed, once the vascular pedicles are ligated, an athermal technique should be used to complete the dissection of the NVB off the prostate. As well demonstrated by Ong *et al.* in the canine model, application of hemostatic energy sources in proximity to the NVB can result in significantly decreased erectile response to cavernous nerve stimulation [36]. We have corroborated these findings in the clinical setting as reported in 2008. In our single surgeon series, comparison of cautery and cautery-free nerve-sparing techniques employed during the first 500 consecutive RARP cases demonstrated an almost five-fold difference in early return of sexual function. At 9 months after surgery, the cautery group was shown to have a potency rate of 14.7%, while the cautery-free group had a potency rate of 69.8% at the same time point. Over time, the cautery group did demonstrate recovery of sexual function; however, the cautery-free group continued to "outperform" in long-term analysis, with a potency rate of 92% (vs 63.2%) at 2 years post-RARP [37].

With the vascular pedicle transected, the interfascial plane between the prostatic capsule and NVB is reliably identified. The prostate is then swept gently off the NVB until it has been released down to the level of the urethra. By completely mobilizing the prostate, the antegrade,

Figure 91.3 Suture ligation of prostatic vascular pedicle.

descending approach allows the surgeon to facilitate the separation of the NVB from the prostatic apex and urethra, an often challenging task.

Since the landmark autopsy study of the pelvic plexus by Walsh and Donker in 1982 [38], the technique of anatomic, nerve-sparing radical prostatectomy has resulted in significant improvements in sexual function outcomes. Since that time, however, several anatomic studies have demonstrated that there may be some variability in the distribution of periprostatic nerves, with nerve tissue being found as high up as the ventrolateral surface of the prostate [39–41]. As such, some authors have advocated a high incision of the lateral prostatic fascia along the ventrolateral aspect of the prostate, leaving what has been described by Menon *et al.* as the "veil of Aphrodite" [42]. The benefits of this high anterior release have not only been shown in RARP but in traditional open RRP as well [43]. However, some have questioned the role of the high anterior release, stating that the anteriorly found nerves mainly innervate the prostate [44–46] with little functional capacity with respect to cavernosal tissue. In addition, these authors claim that improved outcomes from a high anterior release may result from the reduction of traction injury to the posterolaterally placed NVBs. Finally, they also state that the lack of intraoperative electrostimulation studies to corroborate the role of these anterior nerves further questions the impact of high anterior release. Almost as a rebuttal to these arguments, a recent study by Kaiho *et al.* demonstrated that intraoperative electrostimulation at the anterior and lateral borders of the prostate did indeed increase cavernosal pressures [47].

There has also been significant debate as to the impact of an "intrafascial" dissection, as initially described in 2004 [48]. Although some observational studies have reported good erectile function outcomes with this approach [49, 50], others have questioned the benefits of the intrafascial technique [46, 51, 52]. We firmly believe that extensive redundancy exists between the NVBs. Walsh, Catalona, Ahlering and data from the CaPSURE database all demonstrate that if unilateral and bilateral NVB preservation are compared, the improvement in potency rates rises only 1.15–1.35x rather than the anticipated 2x [53–56]. The argument is further supported by the finding that the quality of sexual function recovery as based on five-item International Index of Erectile Function (IIEF-5) scores was identical regardless of number of nerves being spared [55]. Further, redundancy is ubiquitous in nature. Hence, redundancy and logic should dictate that if doubling the volume of nerve preserved increases outcomes by just 25%, then increasing the volume of nerve preserved with an intrafascial approach would only be expected to improve potency by 1–2%. The risk of a positive surgical margin logically speaks against the risk of an intrafascial technique. Recently, Potdevin *et al.* reported that debatable improvement in potency rates may come at the price of oncologic control [57]. We believe an athermal technique

with minimization of traction on the NVB serves to accomplish similar outcomes and conforms to the oncologic principles of a radical prostatectomy.

With the NVB completely mobilized, the urethra is transected sharply several millimeters distal to the prostatic apex. The specimen is then placed in a small entrapment sac, and temporarily positioned in the upper abdomen. The purse-string attached to the entrapment sac is removed through the 12-mm assistant port and secured with a small clamp.

The pneumoperitoneum pressure is then reduced and the NVB is examined for hemostasis. Any small arterial bleeders are controlled with the precise placement of absorbable 4-0 suture ligatures. The vascular prostatic pedicles are also examined for hemostasis, with precise placement of absorbable 3-0 suture ligatures for any evidence of bleeding. It is important to remove the retraction suture, suspending the bladder at this point in preparation for the anastomosis.

Urethral anastomosis

In 2001, the initial teams describing RARP all utilized interrupted sutures to perform the vesicourethral anastomosis [9–11], as they had done in their LRP experiences. However, as luck would have it, van Velthoven *et al.* described the use of a single-knot running suture for RARP [58]. Historically, the urethrovesical anastomosis was the most challenging aspect of LRP or RARP, technically speaking. The van Velthoven stitch, as it is now referred to, allowed for 10 needle placements through the bladder and urethra in a tension-free fashion; five throws from each of the two 7-inch monofilament absorbable sutures. The suture is prepared by tying together the tails of two 7-inch monocril sutures on SH or RB-1 needles. As originally described by van Velthoven *et al.*, once both sutures have been placed, the right and left sutures are cinched up from the bladder gently and securely, approximating the posterior lip of the bladder to the posterior urethra [58]. The critical benefit of this technique is that the initial tension of approximating the bladder to the urethra is dispersed over 10 needle holes rather than two with interrupted techniques. It is simple and creates a watertight anastomosis with only one intracorporeal knot required.

A second critical improvement to the reconstruction of the bladder to the urethra is the Rocco stitch first described in 2006 [59]. Much debate exists as to whether it improves time to continence, but we strongly recommend incorporating the stitch as there is universal agreement that it further facilitates a tension-free anastomosis and is very hemostatic. It adds no more than 3–5 min and in our experience more than 98% of men have clear urine 1 day post surgery. In our experience, patient calls regarding clots and hematuria and visits to the clinic or emergency room have been nearly completely eliminated. Lastly, in our experience since incorporating the Rocco stitch, the bladder neck contracture rate appears to be less then 1 in 500 cases. We recommend a 9-inch, 3-0 absorbable monofilament suture to place a continuous, running stitch between the cut edge of Denonvilliers' fascia, with a small bite of posterior bladder wall, and the posterior external striated sphincter found beneath the urethral stump. By cinching this suture, the bladder is secured about 1–2 cm from the urethra.

Next, the van Velthoven suture is passed into the surgical working field. There has been a slight modification from its initial description: instead of starting at the 6 o'clock position with both needles, we start out-to-in on the bladder at the 4 o'clock position with one needle. In this fashion the preformed knot is found outside on the posterior bladder wall. After five throws have been placed in a clockwise direction, the system of loose loops is cinched together in a winch-like fashion to bring the posterior bladder neck in apposition with the posterior urethra. It is important to always cinch on the bladder side to prevent pull-through; tearing is a problem if the fixed and more flimsy urethra is used. Once the posterior aspect of the anastomosis has been pulled water tight, the suture is then continued clockwise to approximately the 10 o'clock position. The suture can then be held tight by the fourth arm. The needle on the right side of the anastomosis is then used in a similar fashion to place a continuous running suture from the 5 o'clock to 11 o'clock position, in a counterclockwise direction. A transition stitch is placed at the 11 o'clock position in order to tie across the anastomosis.

A Foley catheter is used as a suture guide during the placement of the anastomotic suture, with perineal pressure applied as needed to improve exposure of the urethral stump. Once the anastomosis has been completed, an 18F silastic catheter is placed into the bladder and a total of 10 mL of sterile water is used to inflate the catheter balloon. The bladder is then subsequently irrigated through this catheter to confirm proper placement, to remove blood clots, and to visually inspect for any evidence of anastomotic leakage. The definitive urethral catheter may be inserted prior to placement of the final throw of the anastomotic suture to visually confirm proper placement; however, we believe that when done properly, the catheter passes across the anastomosis without any difficulty.

There have been several other descriptions of techniques used to improve functional continence outcomes post radical prostatectomy [33, 60, 61]; however, we feel the Rocco stitch lends itself best to the RARP procedure. It makes the anastomosis technically easier by stabilizing the posterior structures, dramatically reduces post-

operative hematuria, and may improve time to continence [59]. We have recently reported on the exciting role of local hypothermia in improving continence outcomes after RARP [62]. Taking well-established lessons from cardiac and neurosurgeons in using cooling techniques to stop the inflammatory cascade common to all trauma, iatrogenic or otherwise, the use of an endorectal cooling balloon allows us to locally cool the pelvic region to approximately 50–68° F. Initial studies not only demonstrate an earlier return to continence, but higher "zero pad" rates at 3 and 12 months post RARP. We continue to perform studies addressing the impact of hypothermia on erectile function and examining the role of different cooling regimens on functional outcomes.

A final hemostatic check of the entire surgical field is performed before undocking the robot and removing the prostate specimen through the umbilical port, the easiest port site to close. Minimal enlargement of the umbilical incision in a transverse direction can facilitate the safe and easy removal of the specimen from the surgical field. The entrapment bag and prostate are inspected prior to transfer to pathology and the fascia is then closed with a looped 0 absorbable suture such as PDS (Ethicon, West Somerville, NJ, USA). The assistant ports and the 8-mm robotic ports are not closed. We do not routinely place a surgical drain at the end of the procedure. Recent literature supports this practice [63, 64]; however, drains may be left at the surgeon's discretion. Absorbable subcuticular sutures, skin staples, and/or a biologic adhesive can be used to close the skin incisions.

Pelvic lymph node dissection

For patients with preoperative oncologic parameters mandating the need for pelvic lymphadenectomy, we recommend an extended pelvic lymph node dissection (PLND), as described by Mattei *et al.* [65] and recently discussed by Briganti *et al.* [66]. A full discussion regarding the indications for, and extent of, pelvic lymphadenectomy is not specific to RARP and is beyond the scope of this chapter. However, even if this debate is disregarded, there remain institutional differences regarding the recommended timing of the PLND during RARP. Although some have described performing the PLND at the start of the procedure [27, 67], we prefer to perform the extended PLND after the prostate has been removed, just prior to the vesicourethral anastomosis. With the prostate removed from the pelvis, there is greater exposure of the vessels, facilitating the extended dissection up to the level of the common iliac vessels. Also, by performing the main oncologic portion of the procedure first, any small risk of having to abort the procedure due to inadvertent major vascular injury during lymphadenectomy is avoided. Finally, due to significant improvements in staging imaging, the likelihood of aborting a RARP due to grossly positive pelvic lymph nodes at the time of surgery is vanishingly rare.

Complications

Complications during RARP are often related to surgeon experience, and as such are more common during the initial learning curve. In addition, during the "acceleration phase" of the learning curve, after the surgeon has become proficient in the basics of the procedure and begins to tackle more difficult cases, a temporary increase in complications may emerge.

There are also several patient factors that may influence the rate of complications during RARP, such as obesity, prostate size, history of prostate surgery, etc. With that said, none of these factors is specific to RARP, and indeed all influence outcomes regardless of the approach. As with open RRP, several studies have demonstrated that obese patients undergoing RARP tend to have significantly longer operative times, greater blood loss, higher complication rates, and perhaps worse oncologic and functional outcomes [68–70]. Patients with larger prostates have also been associated with greater blood loss, longer hospital stays, higher complication rates, and worse functional outcomes [71, 72].

As with reporting of oncologic and functional outcomes, the current published literature with regards to complication rates for RARP suffers from a lack of standardization. Based on a few publications using the standardized Clavien system [73] for reporting surgical complications, RARP was associated with an overall complication rate of 12.2–26%, although only 0.5–8.5% of these were Clavien 3 or greater [74–78]. Blood transfusions were required in approximately 1–5% of patients, while urine leak and bowel injury were seen in 4.5–7.5% and 0.6–1.5%, respectively. Due to the lack of standardization, it is difficult to use the currently published literature to make a direct comparison between RARP and open RRP complication rates.

Intraoperative complications

Intraoperative complications can be classified as either access related or procedure specific. Access-related complications are not specific to robotic surgery but are germane to all laparoscopic procedures. We will limit our discussion to RARP-specific complications.

Rectal injuries most commonly occur during the dissection of the prostatic apex. Regardless of whether the posterior dissection is performed at the very start of the procedure, as described by the group from Montsouris [13], or done following transection of the prostatovesical junction, if not completely mobilized off the posterior

aspect of the prostate, the rectum that remains adherent to the apex is at risk of injury during transection of the urethra. Although less common, rectal injuries can also occur during the posterior dissection itself. The key is to use the perirectal fat as a guide to stay in the correct plane, dissecting close to the prostatic surface. Finally, when performing non-nerve-sparing RARPs for aggressive high-risk prostate cancer, lateral rectal injuries may occur while performing wide resection of the NVBs, particularly at the apex.

Ureteric injuries, though uncommon, can occur at several different stages of the procedure. First, when dissecting the posterior aspect of the prostatovesical junction, care must be taken with the ureteral orifices located nearby. The interureteric ridge, also known as Mercier's bar, can be used as a landmark to identify their location. In patients with a large median lobe, identification of the orifices may be difficult for the novice surgeon. As such, we recommend avoiding these types of patients during the early learning curve. The second stage where ureteric injuries may occur is during the anastomosis. Particularly when the posterior wall of the bladder has been somewhat thinned, surgeons tend to take large bites of the posterior wall with their anastomotic suture in the hope of buttressing the thinned wall. It is important to note that the intramural portion of the ureter must not be included in the suture, particularly when the ureteric orifices are found close to the cut edge of the bladder neck. Finally, the ureter can also be injured during the PLND, as it courses over the iliac vessels.

Other intraoperative complications can occur during the PLND, including major vascular injuries and obturator nerve injuries. Although uncommon, these types of complications can lead to significant patient morbidity. They can occur due to inappropriate direct application of electrocautery, inadvertent direct ligation, coupling of energy to another instrument, or sheer force trauma during blunt dissection. In addition, iliac vessels can be injured during uncontrolled, blind robotic instrument insertion or exchange. Despite these potential complications, several studies have demonstrated that PLND can be safely and effectively performed during RARP [79, 80].

Postoperative complications

Early postoperative complications include urinary tract infections, anastomotic urine leaks, hemorrhage, ileus, deep vein thromboembolism, and peritonitis from unrecognized bowel injury.

Studies have demonstrated that RARP, when compared to open RRP, is associated with significantly less blood loss and a lower risk of requiring blood transfusions [81–87]. This is likely a cumulative result of the improved visualization of the DVC afforded by the da Vinci robot, the ability to accurately identify and precisely ligate bleeding vessels, as well as the effects of the pneumoperitoneum tamponading small venous bleeders. Nonetheless, the need for transfusion following RARP is not nil and vigilance is required in the early postoperative period.

Due in part to the lack of standardized reporting, but also related to the fact that many RARP surgeons do not leave a postoperative drain, the true incidence of anastomotic urine leaks is unknown. Based on published literature, however, it is likely to be in the 5% range [74–78].

Although extremely rare, transient femoral nerve palsies related to positioning have been noted [88]. In our single-surgeon series of almost 1000 cases, we have also noted this on rare occasion, and anecdotally note an association with muscular men who have bulky muscle mass in their lower limbs.

As in open surgery, urinary incontinence and erectile dysfunction continue to be the most common and noteworthy late complications following RARP. The multifactorial nature of both these postoperative rates suggests that patient selection plays just as much a role as any technical or surgeon-related factor. A detailed discussion of functional outcomes after RARP follows in Chapter 92. It should be noted, however, that due to a significant lack of standardization in the published literature with regards to the reporting of these outcomes, as well as the limited use of validated instruments to measure the prevalence of these complications, direct comparisons between RARP series, as well as against open RRP series, are difficult and unreliable.

Bladder neck contractures, lymphoceles, inguinal hernias, and port-site hernias have also been reported. Perhaps, in part, a reflection of the slightly lower rates of anastomotic urine leaks, bladder neck contracture rates also seem to be lower following RARP than open RRP [81, 83, 89, 90].

Outcomes

Oncologic outcomes

Above all, RARP remains an oncologic procedure with curative intent. Some authors have been very vociferous in criticizing the early adoption of RARP without long-term oncologic data to support such widespread application. Although this may have held early merit, recent short- and intermediate-term oncologic data point towards comparable outcomes to standard open RRP. There is no doubt that oncologic data are more robust with traditional RRP; however, as demonstrated by several institutions, RARP seems to be establishing its merits as a valid option in the surgical management paradigm of localized prostate cancer.

In a systematic review of comparative studies published in 2008, the authors found no significant between-group differences in overall risk or incidence of positive surgical margins (PSMs) in patients undergoing open RRP, LRP, and RARP [85]. In a single-institution study by Schroeck *et al.*, the authors also found no significant difference in PSM rates between RARP and RRP on both univariate and multivariate analyses [90]. Interestingly, Smith *et al.* published a report in 2007 which demonstrated that RARP was associated with a significantly lower PSM rate than open RRP: 15% and 35%, respectively [91]. Similarly, a systematic review of comparative studies by Ficarra *et al.* noted a significantly lower PSM rate among those undergoing RARP compared to RRP [92].

Some authors have debated the true impact of PSM after prostatectomy, citing biochemical recurrence and disease-specific survival as better oncologic markers. In a large study by Krambeck *et al.*, there was no difference in biochemical progression-free survival at 3 years after RARP and RRP: 92.4% and 92.2%, respectively [93]. Barocas *et al.* demonstrated similar findings in another single-institution comparison of RARP and RRP where the 3-year biochemical recurrence-free survival was 84% and 83.5%, respectively. In this study, the cohort undergoing RRP had higher-risk features; however, on multivariate analysis procedure type was not a significant predictor of biochemical recurrence [94].

Through careful patient selection and rigorous surgical technique, outcomes for RARP can be optimized to maintain the curative intent of this procedure (Table 91.2). As with open surgery, a meticulous dissection in adherence to sound oncologic principles must be ensured, particularly at the apex of the prostate. In addition, the use of preoperative information such as site-specific biopsy results and findings on digital rectal examination to guide the dissection is crucial in achieving this goal.

Functional outcomes

As discussed earlier, the literature is rife with publications reporting on functional outcomes following radical prostatectomy that lack standardization. In addition, many studies employ nonvalidated instruments or questionnaires in measuring continence and erectile dysfunction rates. As an example, it is the authors' firm belief that "0–1 pads" and "one security pad only" is significantly different from "pad-free" continence. To this effect, using patient-administered, validated questionnaires, Liss *et al.* demonstrated that quality-of-life scores decreased significantly between "no pads" and "security pad" or "0–1 pad" [95].

As such, direct comparative analyses and generalizability of data are difficult. That said, the majority of large series published on RARP demonstrate continence and erectile function outcomes comparable to the robust data of open RRP [27, 85, 90, 93]. Interestingly, there are several reports that may suggest an earlier return of continence and sexual function after RARP, which is encouraging [87, 96]. In contradistinction, a highly publicized study by Hu *et al.* reported a significantly higher rate of incontinence (15.9 vs 12.2 per 100 person-years) and erectile dysfunction (26.8 vs 19.2 per 100 person-years) after "minimally-invasive radical prostatectomy." Unfortunately, this study was based on Current Procedural Terminology (CPT) codes only, without the use of any validated instruments, and grouped RARP and LRP together in the analysis [81]. In addition, the two groups were significantly different prior to propensity weighting.

Many different dissection techniques have been described in the literature in attempts to improve functional outcomes following RARP (a more detailed discussion on outcomes can be found in Chapter 92); however, a basic principle can be found among many of these descriptions. Whether through the use of athermal

Table 91.2 Technical tips for robot-assisted radical prostatectomy.

Technique	Rationale
Placement of bladder retraction suture	Improves working space in the pelvis Protects bowel from iatrogenic injury
Removal of anterior prostatic fat	Improves visualization of the dorsal venous complex, allowing for more distal ligation
Antegrade dissection of neurovascular bundles with minimal traction	Reduction of trauma to nerve tissue
Use of van Velthoven suture for vesicourethral anastomosis	Technically easier than interrupted sutures Improved water-tight anastomosis
Transverse umbilical incision to remove prostate specimen	Decreased rate of port-site hernias Improved cosmesis

techniques, the avoidance of excessive traction, seminal vesicle-sparing dissections, or the use of locoregional cooling strategies, the reduction of inflammation and injury to key structures is vital in preserving and optimizing functional outcomes.

For more experienced RARP surgeons who have optimized and standardized their surgical technique, patient factors likely play a larger role in predicting functional outcomes than any specific technical nuance or strategy. Variables such as patient age and preoperative functional status are strong predictors of outcomes. As an example, the five-item International Index of Erectile Function (IIEF-5) score correlates well with postoperative erectile function and likely serves as a strong surrogate marker of overall health and vitality. In addition, although to date there is a relative paucity of literature regarding this issue, the role of serum androgen levels in predicting functional outcomes is an interesting and exciting avenue of research.

Outcomes self-assessment

It is imperative for the robotic surgeon to establish a surgical database of preoperative demographics and postoperative outcomes for critical self-evaluation. Self-assessment is a continual iterative process, and as the volume of cases increases, a personal database allows the surgeon to quickly measure themselves against published results. Through the process of self-assessment of outcomes, the surgeon can decide if there are specific troublesome technical or clinical issues. There are two important self-assessment tools: video recording of cases and rigorous data collection.

Digitally recording each case can be extremely advantageous not only to the novice surgeon but to those with experience as well. Reviewing the operation in realtime is particularly useful for difficult cases, complications, and PSMs. Also, cases with excellent functional outcomes can be reviewed for positive reinforcement of successful techniques. As demonstrated by several groups, a surgeon reviewing video-taped footage of their surgical performance can have a positive impact on improving and evolving their surgical technique [97–100].

Data collection of patient demographics and outcomes is also essential to truly understand the success or failure of robotic surgery. A proposed minimum data collection design is shown in Table 91.3. Preoperative data must be stringently collected as most functional outcomes may be dependent on the baseline characteristics of the patient. Preoperative data also give the surgeon a benchmark, as the ideal goal is to restore all men to preoperative functional status. Postoperative oncologic and functional data, in addition to complication rates, should be meticulously recorded if the surgeon hopes to be critical of their technique and improve surgical performance. In order to determine the true place of robotics in the surgical pantheon, validated questionnaires and analog assessment scales are essential in determining true functional results, and need to be combined with careful long-term follow-up of oncologic outcomes.

The thorny issue of statistical analyses should be explored early through consultations with an expert statistician. This relationship will make the proposed data collection more effective and efficient. As sexual potency and continence outcomes will not be available until 6–12 months into the surgeon's RARP experience, preconsultation with a statistician regarding data collection methods is a strategic and time-saving advantage for any program.

Table 91.3 Suggested data collection.

Preoperative
Patient information (age, body mass index, etc.)
Number of positive biopsy cores and location(s)
Clinical stage
Clinical Gleason score
Prostate-specific antigen (PSA) level
Prostate size by transrectal ultrasound
Sexual Health Inventory for Men (SHIM), five-item International Index of Erectile Function (IIEF-5)
Operative
Operating room time
Estimated blood loss
Hospital stay
Complications
Postoperative
Positive surgical margin and location(s)
Pathologic Gleason score
Prostate weight
PSA level/recurrence
SHIM score/IIEF-5
International prostate symptom score (IPSS)/American Urological Association score
Urinary bother score
Daily pad usage for continence/EPIC

Conclusions

Minimally invasive surgery in urology has come a long way since the initial description of the laparoscopic

nephrectomy 20 years ago. Through advances in technology, engineering and science, urologists are now able to offer patients ever more optimized care with minimized morbidity.

The early, widespread adoption and application of RARP into the prostate cancer management paradigm was criticized by some for its lack of substantiating evidence both in safety and effectiveness. However, with the maturation of technology, surgeon skill level, and outcomes data, evidence suggests that not only is RARP a safe option for patients with prostate cancer but perhaps, in certain respects, a more effective one as well.

Looking forward, RARP is a new technology that seems to be here to stay. It is up to robotic surgeons themselves to ensure the safe and effective training in and application of this technology to improve patient outcomes. In addition, it behooves us to employ self-assessment strategies, use validated instruments, and standardize reporting of both outcomes and complications so that we can improve upon current results with this technology. Above all else, it must be kept in mind that in the prostate cancer management decision analysis process, it is the decision to operate that is the key issue, not the incision.

CHAPTER 92

Optimizing Outcomes During Laparoscopic and Robot-Assisted Radical Prostatectomy: Oncologic Concerns, Potency, and Continence

Daniel Willis[1] & Li-Ming Su[2]

[1]Department of Urology, University of Florida College of Medicine, Gainesville, FL, USA

[2]Robotic and Minimally Invasive Urologic Surgery, Department of Urology, University of Florida College of Medicine, Gainesville, FL, USA

Introduction

The initial description of radical prostatectomy dates back to 1905 when Hugh Hampton Young performed the first radical prostatectomy for cancer through a perineal approach. In 1947 Millin was credited with describing a retropubic approach to prostatectomy. At that time, many patients presented with palpable cancers and therefore were not cured by radical prostatectomy alone. They also suffered from severe urinary incontinence and complete impotence. It was not until the late 1970s and early 1980s, when a more anatomic approach to radical retropubic prostatectomy emerged as a result of a greater appreciation of the striated urethral sphincter [1] and neurovascular bundle (NVB) [2], that postoperative continence and potency improved. This was followed by the development of minimally invasive approaches to radical prostatectomy that included laparoscopic prostatectomy (LRP) and robot-assisted laparoscopic prostatectomy (RALP).

LRP was first described in 1996 in a canine model [3]. The first human series was published 1 year later by Schuessler *et al*. [4] and later modified in 2000 [5, 6]. RALP was first described by several centers in Europe in 2001 [7–9] and later popularized in the USA by the work of Menon *et al.* in 2002 [10]. RALP and LRP have maintained the oncologic and functional outcomes of open surgery, but with a reduction in blood loss, transfusion rates, and postoperative convalescence [11]. The vast majority of radical prostatectomies in the USA are now performed using a minimally invasive approach.

The implementation of prostate cancer screening with the use of prostate-specific antigen (PSA) testing in the late 1980s resulted in the detection of cancers more likely to be confined to the prostate gland, and therefore more likely to be cured by prostatectomy. This has led to increased focus and attention on functional outcomes after radical prostatectomy. Accordingly, the quest for the perfect "trifecta" of cancer cure and preservation of complete continence and potency has caused several groups to review their experience and outcomes with radical prostatectomy. Bianco *et al.* reported on 1746 patients who underwent open radical retropubic prostatectomy with a mean follow-up period of 6 years. Although 83% of the men had effective cancer control, only 60% attained the perfect trifecta after 2 years following surgery as most were affected by erectile dysfunction [12]. Shikanov *et al*. in 2009 reviewed 380 patients who underwent RALP. They reported that only 44% of patients achieved the perfect trifecta at 2-year follow-up according to strict definitions of functional outcomes based upon validated quality-of-life surveys [13].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

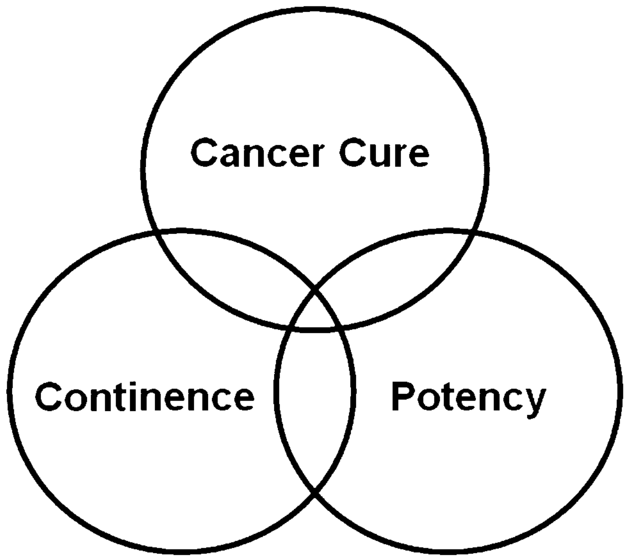

Figure 92.1 The "trifecta": competing goals of radical prostatectomy.

The three postprostatectomy outcomes of cancer cure, urinary continence, and potency are in reality competing goals, where optimization of one outcome may come at the expense of another (Figure 92.1). Furthermore, the possibility of the perfect trifecta may not be realistically achieved in all men due to factors related to the extent and aggressiveness of the cancer, including PSA, volume, grade, and stage of disease. For example, cancers with more aggressive features may warrant a more extensive local surgical excision (i.e. wide excision) to eradicate all cancer, which may concurrently jeopardize the functional outcomes of continence and especially potency.

As a result of the enhanced visual perspective of surgical anatomy with LRP and RALP, there have been many investigations revisiting the neuroanatomy involved in penile erections and the support mechanisms involved in urinary continence. In turn, surgical modifications to RALP and LRP have been introduced over the last decade to optimize both oncologic and functional outcomes, which also appear to improve the trifecta outcomes, particularly after RALP [14]. These concepts will be the subject of this chapter.

Optimizing oncologic outcomes

Surgical margin status and biochemical recurrence have generally been relied upon as surrogates for oncologic efficacy following radical prostatectomy. Multiple factors can influence positive surgical margin rates, including grade and stage of disease, surgeon experience, pathologic analysis, and surgical approach. The most significant factor that determines the positive margin rate in a given series is patient selection. Use of prediction tools and nomograms has allowed for risk stratification and better selection of patients who have organ-confined cancers and thus are more likely to benefit from surgery [15–17]. For example, patients with very high-risk disease can be informed that surgery or radiation alone may not be sufficient and that a multimodality approach to treating their particular cancer may be required. On the other hand, patients with low-volume and -grade disease are at lower risk and are therefore more likely to be cured with a greater likelihood of preservation of quality of life.

Surgeon experience has been identified by some to have a strong association with surgical margin status [18]. Inherent in a surgeon's evolving experience with prostatectomy is their willingness to critically evaluate and track positive surgical margin rates and address potential causes and technical modifications for improvement. To this end, stage-stratified margin rates can provide a surgeon with critical information as to which positive margins may be attributable to technical error (i.e. pT2 disease) as opposed to the aggressiveness of disease (i.e. ≥pT3 disease). Moreover, site-specific positive margins can provide important insights as to the effect of cavernous nerve preservation, bladder neck preservation, and maximization of functional urethral length on posterolateral, bladder neck, and apical margins, respectively. Table 92.1 summarizes the stage-specific positive margin rates for LRP and RALP. In most series, the positive margin percentages decrease with greater experience and familiarity with the procedure.

Surgical technique during both laparoscopic and radical prostatectomy can also influence positive surgical margins at site-specific locations, including the apex, bladder neck, and posterolateral border of the prostate.

Prostatic apex

The prostatic apex is the most common site of positive surgical margins in most reported series. LRP and RALP both allow excellent apical visualization of the prostate to facilitate a meticulous dissection. By fully exposing the prostatic apex after dividing the puboprostatic ligaments, the deep dorsal venous complex (DVC) can be either suture ligated or stapled close to the pubis and well away from the prostatic apex. This reduces the chance of an iatrogenic positive surgical margin from occurring when a surgeon divides the dorsal vein. In cases where the puboprostatic ligaments are not sufficiently divided, the dorsal vein suture or staple line may end up too close to the prostatic apex. As a result, the surgeon may divide the dorsal vein too close to the prostatic apex in attempts to avoid cutting the previously placed suture. This may result in iatrogenic entry

Table 92.1 Reported pT2 and pT3 stage-specific positive margin rates for laparoscopic radical prostatectomy and robot-assisted laparoscopic prostatectomy.

into the prostate apex with a capsular incision, or worse still, leave residual prostate tissue on the dorsal vein stump. Ahlering *et al.* noted in their series a significant decline in T2-positive margins from 27% to 4.7% ($P = .003$) with modifications to apical preparation, including division of the puboprostatic ligaments followed by stapling of the DVC [19]. It is also important to note that considerable variation exists in the shape and contour of the prostatic apex [20, 21]. Protrusion of the prostatic apex beneath the urethra is a unique anatomic variation that warrants special consideration. In such cases, the posterior lip of the prostatic apex develops asymmetric to the anterior apex and thus protrudes beneath the urethra. When dividing the prostatourethral junction, it is important to anticipate this anatomic variation so as not to divide the urethra flush with the prostatic apex and leave residual posterior apical prostate tissue behind. Instead, a more tangential resection is required in such cases so as to ensure complete excision of the posterior prostatic apical tissue.

Bladder neck

Patients with high-volume tumors located at the base of the prostate may be at higher risk of bladder neck involvement. In such cases, wider excision of the bladder neck (i.e. nonbladder neck-sparing procedure) may be prudent to decrease the risk of a positive bladder neck margin. Although wide excision at the bladder neck may in theory compromise the time to recovery of postoperative urinary continence, simple closure of the redundant bladder neck opening in conjunction with modifications to the support of the vesicourethral anastomosis (as described in more detail in the section on Optimizing urinary continence outcomes below) have led to excellent continence rates.

Posterolateral margin and neurovascular bundles

Perhaps the most challenging technical step of prostatectomy lies within the intent to eradicate all cancer while preserving the NVBs for the sake of preserving postoperative erectile function. Recent enthusiasm for more "aggressive" preservation of the NVBs (as discussed in the section on Optimizing potency outcomes) has been noted by some groups to be associated with an increase in positive surgical margins as a result of closer dissection along the prostate surface [22]. The prediction of extracapsular extension of cancer along the posterolateral border of the prostate can be challenging, especially in the era of PSA screen-detected cancers where microscopic and multifocal disease are more commonly encountered as compared to palpable cancers. As such, the relative unpredictability of location and focality of tumor presence makes intraoperative decision-making challenging, especially during the steps of NVB preservation. Furthermore, the lack of haptic feedback with current laparoscopic and robotic technology and the loss of the ability to palpate the prostate surface and detect areas of induration may in theory compromise the ability of a surgeon to adjust the plane of dissection to avoid an iatrogenic positive margin. In efforts to address these issue, Satake *et al.* recently reported on their nomogram for predicting extracapsular extension based upon standard clinical factors (clinical stage, serum PSA, highest Gleason score) and biopsy features (such as maximum percent of cancer in the biopsy cores),

concluding that these parameters could help accurately identify which patients are most suitable to undergo cavernous nerve preservation [23]. In addition to risk stratification, we advocate performing a thorough digital rectal examination with the patient fully anesthetized at the beginning of the operation and before initiating LRP or RALP, in order to gain incremental information as to the presence (or absence) of palpable disease along the posterolateral border of the prostate.

In the end, having a thorough appreciation of each individual patient's unique anatomic nuances and challenges will allow a surgeon to optimize cancer control, while preserving urinary and sexual function in the quest for the perfect "trifecta" [21].

Optimizing potency outcomes

Technical modifications to optimize potency outcomes for LRP and RALP depend on an accurate understanding of the anatomic distribution of the cavernous nerves responsible for penile erection. Walsh and Donker are credited with the initial discovery of nerve fibers that run adjacent to the prostate gland to the penile bodies [2]. The discovery of these extraprostatic nerve bundles would later prove to contain the cavernous nerves responsible for penile erection. In 1998, Walsh published his findings from dissections in stillborn male infants and step-section, whole mount adult cadaveric studies of the autonomic innervation to the bladder and prostate. This would eventually lead to the current surgical approach of anatomic nerve-sparing prostatectomy which aims to preserve the delicate postganglionic parasympathetic fibers of the cavernous nerves [24]. However, several important studies published between 2004 and 2005 have since shown greater complexity to the anatomic distribution of the cavernous nerves than previously thought [25–27]. These studies demonstrated that the periprostatic nerves appear to be more diffuse and variable than initially thought, and include accessory nerve branches that travel along the anterolateral border of the prostate within the periprostatic fascia (Figure 92.2).

These neuroanatomic studies have led to changes in the approach to nerve-sparing prostatectomy, which attempt to increase both *quantitative* and *qualitative* nerve preservation. A modification addressing improved *quantitative* preservation of the cavernous nerves involves incising the levator fascia along the anteromedial portion of the prostate rather than the traditional posterolateral location (Figure 92.2). A plane is then created and extended in a posterolateral direction along the prostatic fascia, extending from the base of the seminal vesicles toward the apex of the prostate. This technical modification attempts to preserve a broad sheet of neurovascular and periprostatic tissue, which should include any accessory nerves that take a more anterior course in addition to the cavernous nerves

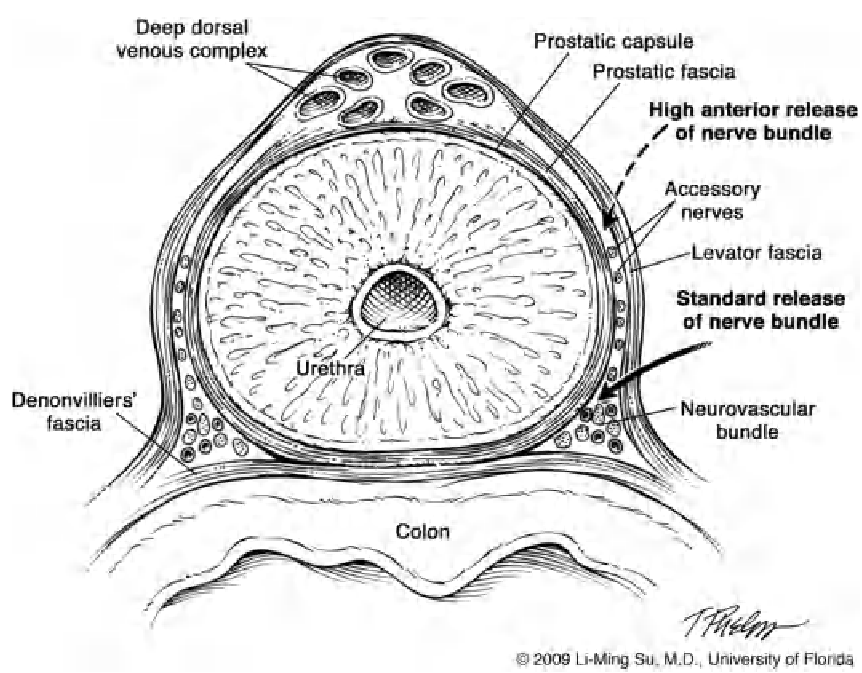

Figure 92.2 Anatomic relationship of the neurovascular bundle (NVB) and accessory nerves to the periprostatic fascia. A high anterior release of the NVB is performed by incising the levator fascia along the anteromedial border of the prostate as opposed to the standard posterolateral release of the NVB along the posterolateral surface of the prostate.

traveling within the traditional NVB, thus leading to an increased *quantitative* nerve preservation. However, it should be noted that the relative contribution, if any, of these accessory nerve fibers to penile erection remains controversial [26]. Several terms have been used to describe this modification including the "veil of Aphrodite" [27], "curtain dissection" [28], and "high anterior release of the levator fascia" [29].

Studies evaluating the effect of increased *quantitative* nerve preservation are limited, with some showing improved potency when compared to conventional cavernous nerve preservation. In 2005, Menon *et al*. compared their "veil of Aphrodite" technique to conventional nerve preservation during RALP [30]. At 12 months, 97% of patients receiving the "veil of Aphrodite" nerve preservation reported successful intercourse versus 74% of men receiving the standard nerve-sparing procedure (P = .002). The same group later used an S-100 nerve stain to evaluate the number of nerves remaining within the periprostatic fascia of the surgical specimens. In the conventional group, a mean of 10 nerve bundles were identified compared to only two bundles in the "veil of Aphrodite" group, suggesting that more periprostatic nerves remained *in situ* in the "veil" group [31], where greater potency outcomes were observed. This study suggests that preserving a greater number of nerves that travel within the anterolateral periprostatic fascia leads to greater postoperative potency.

Nielsen *et al*. also studied cavernous nerve preservation using a similar dissection termed the "high anterior release" of the levator fascia. They evaluated postoperative potency using the Sexual Health Inventory for Men (SHIM). Patients undergoing high anterior release were more likely to achieve a SHIM score of 16 or greater at 1 year after radical prostatectomy when compared to the traditional nerve-sparing technique (93% vs 77%, P = .007) [29]. Percent return to baseline in patients with SHIM scores of greater than 21 was also greater in the high anterior release group among patients who were sexually active (78% vs 52%, $P < .05$). This improved outcome in potency did not increase the likelihood of a positive surgical margin. In their discussion, Nielson *et al*. postulated that the high anterior release of the periprostatic fascia served to better define the posterolateral prostatic plane for improved, tension-free preservation of the conventional NVB, rather than contributing itself to quantitative nerve preservation. Lastly, it should be noted that others have reported no improvement in potency when comparing a high, intrafascial nerve dissection (curtain dissection) to the conventional dissection of the NVB in a series of 310 LRP patients (potency defined as SHIM > 11; 68.4% vs 67.2% at 1 year, P = 1.0) [32].

The quantity of cavernous nerves preserved during prostatectomy is also dependent upon the plane of dissection used during nerve preservation and whether an *extra*fascial, *inter*fascial or *intra*fascial approach is used. Extrafascial dissection represents a wider excision around the prostate gland, maintaining all layers of periprostatic fascia covering the prostate. This technique involves complete excision of the NVB and is utilized in patients in whom a higher risk of extracapsular extension of tumor along the posterolateral surface of the prostate is suspected. During interfascial dissection of the NVB, a plane is developed between the levator fascia and prostatic fascia, and represents the recommended plane of dissection used during conventional preservation of the NVB (Figure 92.3). Lastly, an intrafascial dissection involves releasing the NVBs one layer closer to the prostate by dissecting between the prostatic fascia and the prostatic capsule in order to further optimize cavernous nerve preservation. This dissection, however, should be used selectively in patients with low-volume and low-grade tumors as closer dissection to the prostate capsule may risk an increased rate of positive surgical margins. Potdevin *et al.* compared an athermal intrafascial nerve-sparing robotic prostatectomy to a conventional interfascial nerve-sparing robotic prostatectomy. While the intrafascial group was more potent at 9 months (91% vs 67%, $P < 0.01$), the pT3 positive surgical margin rates were almost double (41% vs 22%, $P < .05$) [22]. This was later supported in a study incorporating extraperitoneal/endoscopic (RALP and LRP) radical prostatectomies that randomized patients to inter- versus intra-fascial nerve dissection. The intrafascial group was again more potent at 12 months (83% vs 65%, P = .005), while the pT3 positive surgical margin rates were also higher in the intrafascial group, though statistical significance was not reached (32% vs 26%) [33]. In surgical practice, however, intraoperative findings, such as suspicious appearance of tissue or adhesions adjacent to the NVB, may warrant deviation from the anatomic dissection along these periprostatic fascial planes. In such cases, partial or "incremental" nerve preservation in the regions of concern can be performed to avoid complete and wide excision of the entire NVB. In support of this, a study by Levinson *et al.* noted that a surgeon's subjective characterization of the relative quantity of nerves preserved correlated with objective postoperative recovery of potency [34]. In the end, surgeon experience and judgment guided by clinical parameters such as digital rectal examination (i.e. clinical stage), tumor volume and location, grade, PSA, and intraoperative findings should be used collectively to determine the optimal plane of cavernous nerve preservation to optimize potency outcomes without jeopardizing cancer cure [17, 23]. Table 92.2 summarizes the reported potency outcomes after LRP and RALP.

In addition to a focus on the *quantitative* aspect of preservation of the NVB during prostatectomy, greater

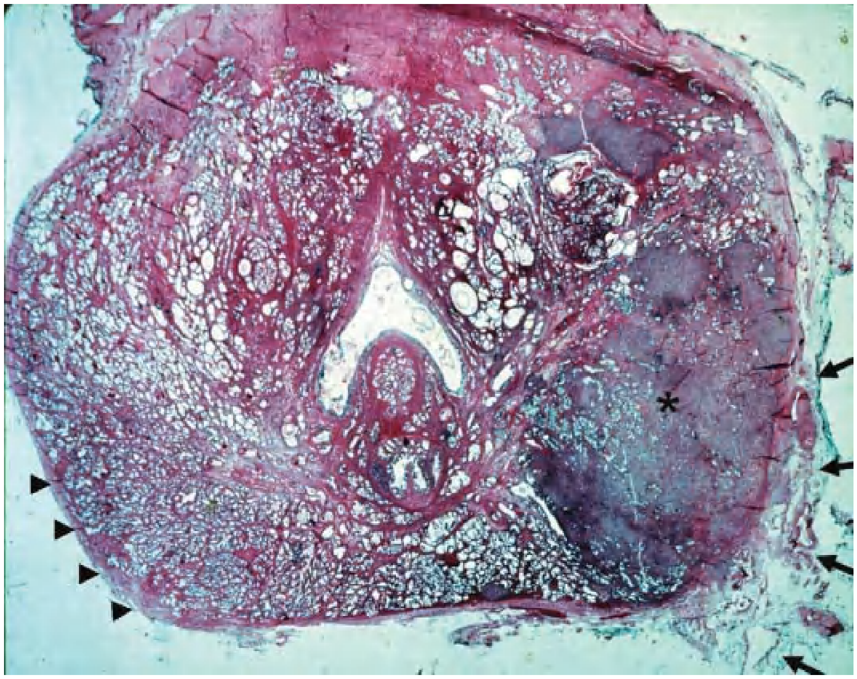

Figure 92.3 Whole-mount section of a prostatectomy specimen demonstrating the difference between an interfascial (left side) and extrafascial dissection (right side) of the neurovascular bundles (NVBs). Note the high-volume cancer (*) on the right lobe closely approximating the NVB, which has been excised along with the prostate by an extrafascial dissection (arrows). In contrast, no NVB remains on the left posterolateral surface of the prostate where interfascial dissection was performed with preservation of the NVB (arrowheads).

emphasis has also been placed on improving the *quality* of the nerve preservation. *Qualitative* nerve preservation relates to the handling of the NVB during dissection with emphasis to avoid stretch and thermal injury. The use of extensive thermal energy during LRP and RALP prompted Ong *et al.* to study the effect of thermal injury on cavernous nerve function in a canine model. They found that all forms of thermal energy, including ultrasonic shears, and bipolar and monopolar electrocautery, caused injury to the sensitive postganglionic parasympathetic fibers of the canine cavernous nerves [35]. This was demonstrated by an absolute reduction in the magnitude of stimulated erections, with no further recovery noted 2 weeks following cavernous nerve thermal injury. These findings were supported in a human study by Ahlering *et al*. using a cautery-free nerve-sparing technique that showed greater early potency rates at 3 months when compared to dissection using bipolar electrocautery (47% vs 8.3%, $P < .001$) [36]. However, in a follow-up study, the same group reported that the thermal and cautery-free groups showed no significant difference in potency at 2 years, suggesting that the insult to the cavernous nerves may be due to neuropraxia rather than permanent injury [37]. As a result, the effect of thermal injury on cavernous nerve function has led to the adoption of an "athermal" approach to nerve preservation in order to maximize early return of post-prostatectomy potency.

Erectile function is impaired following radical prostatectomy even after the most meticulous nerve-sparing dissection. Some degree of neuropraxia is unavoidable because of the close proximity of the NVB to the prostate gland. The recovery of the cavernous nerves is very slow and may take as long as 3 years before baseline function is reached [38]. Meanwhile, a lack of erections leads to a series of events which can culminate in tissue hypoxia and apoptosis with a resultant decrease in penile size and cavernosal fibrosis. This has led to the concept of postprostatectomy penile rehabilitation to enhance penile vascularity and integrity of the corporal tissues with the hope of maximizing postoperative recovery of erections.

The pathophysiology of postprostatectomy erectile dysfunction is multifactorial and has been elucidated in both animal and human models [39]. Initial postoperative neuropraxia leads to a lack of erections, which leads to decreased blood flow and poor oxygenation to the corporal bodies. This diminished penile blood flow is further compounded by a reduction in arterial inflow to the penis after ligation of accessory internal pudendal arteries during prostatectomy. This leads to hypoxia within the penis, which sets off a cascade within

corporal smooth muscle cells resulting in apoptosis, muscular constriction, and deposition of collagen resulting in fibrosis and venous leak. The goal of postprostatectomy penile rehabilitation is to stimulate the penile erectile tissues, increase tissue oxygenation within the cavernosal bodies, and decrease fibrosis and apoptosis to improve postoperative recovery of normal erectile function. The impact of penile rehabilitation has been very encouraging in the animal model, but has yet to be replicated in clinical studies where short follow-up and poor patient compliance is prevalent. One encouraging study from Mulhall *et al*. suggests that delaying post-prostatectomy penile rehabilitation beyond 6 months is associated with poorer potency outcomes at 2 years when compared to patients who start penile rehabilitation early (sildenafil-assisted functional erections 45% vs 86%, $P < .01$) [40]. The ideal combination of rehabilitation strategies remains controversial, but early and aggressive penile rehabilitation has become standard practice for many urologists in treating patients who have undergone radical prostatectomy. Although a general consensus has been supported by many andrologists in the field that penile rehabilitation is beneficial, there still remains insufficient evidence as to the precise timing, duration, and ideal rehabilitation protocol, whether it be the use of phosphodiaesterase-5 inhibitors, vacuum erection devices, intraurethral or intracavernosal therapies, or a combination thereof [41].

Optimizing urinary continence outcomes

Urinary incontinence represents a major factor affecting daily quality of life after radical prostatectomy. As a result, there have been continued efforts to refine and modify the surgical technique to restore the vesicourethral anastomosis as close to the presurgical state as possible. Table 92.3 summarizes the reported continence outcomes after LRP and RALP.

Reconstruction of the vesicourethral anastomosis has been compartmentalized to posterior and anterior support. The primary maneuver to reinforce the posterior aspect of the vesicourethral anastomosis was first described by Rocco *et al*. in 2006, who reapproximated the urethral sphincteric complex with an absorbable suture by joining posterior detrusor muscle to remnant Denonvilliers' fascia and then to the posterior median raphe of the rhabdosphincter (Figure 92.4) [42]. As a result of prostatectomy, there is a foreshortening of the urethral sphincteric complex with resultant caudal prolapse and loss of posterior fixation of the rhabdosphincter. The "Rocco stitch" is thought to facilitate continence by re-establishing posterior anatomic support to the bladder and urethra during voiding, increasing the functional length of the rhabdosphincter, and reducing tension on the vesicourethral anastomosis. The Rocco stitch also enhances the vesicourethral anastomosis by improving access and visualization to the urethral stump by reducing caudal migration of the urethra during suturing of the vesicourethral anastomosis. This is particularly advantageous during LRP and RALP where the reapproximation of the urethra and bladder neck is performed under direct visualization. Additional theoretical benefits of this stitch include tamponade and reduction of venous bleeding along the bed of the prostate, and prevention of anastomotic disruption in the event of a pelvic hematoma. This modification to the posterior support of the anastomosis was originally applied to open radical retropubic prostatectomy and resulted in an earlier return to continence when compared to a standard anastomosis without reconstruction. At 3, 30, and 90 days after Foley catheter removal, Rocco *et al.* reported continence rates of 72%, 79%, and 86% compared to 14%, 30%, and 46% in the standard prostatectomy group ($P < .001$). Interestingly, at 360 days, the continence rates between the two groups were not significantly different (95% vs 90%, $P > .05$), suggesting that the Rocco stitch may promote an earlier return to continence rather than improving overall long-term continence rates [42].

Reinforcement of the anterior support of the vesicourethral anastomosis has also been described for RALP [43]. This involves resuspension of the anterior anastomosis and distal bladder neck to the arcus tendineus with the goal of restoring anterior urethral support with preservation of the vesicourethral angle. The technique of joining the anterior and posterior reconstructions (modified Rocco stitch) was termed the "total reconstruction of the vesicourethral junction" by Tewari *et al.* who compared the total reconstruction method during robotic prostatectomy to patients receiving no reconstruction or anterior reconstruction only. In this study, continence was defined as using no pads or just one liner a day for security. The median time to continence for patients undergoing total reconstruction was 3 weeks, with a continence rate of 97% at 24 weeks. The percentage of continent patients in the total reconstruction group was significantly greater at all time points when compared to patients with no reconstruction or anterior reconstruction only (97.1% vs 62.0% vs 85.7%, respectively, at 24 weeks, $P < .001$)). In contrast, Menon *et al.* found no significant benefit from their combined anterior and posterior reconstruction in a prospective, randomized controlled study when compared to patients without any reconstruction [44]. Their continence rates after more than 3000 robotic prostatectomies using 0–1-pad and zero-pad continence criteria were 80% vs 74% ($P > 0.1$) and 42% vs 47% ($P > 0.1$), respectively. Despite these results, Menon *et al*. continue to perform reconstruction of the vesicourethral anastomosis as they have

noted a benefit in reducing urinary extravasation detected on routine postoperative cystogram studies.

In addition to reconstruction of the vesicourethral anastomosis, reconstruction of the bladder neck has also been described as a means of improving postoperative continence rates. In 2002, Walsh described intussusception of the bladder neck by the placement of two figure-of-eight sutures within the perivesical tissue, one posteriorly and the other anteriorly, both of which are located 1–2 cm proximal to the bladder neck [45]. This bladder neck intussusception technique is believed to create a "collar" of perivesical tissue surrounding the bladder neck, which serves to increase bladder neck resistance and prevent passive opening (and thus incompetence) of the bladder neck during bladder filling. In Walsh and Marschke's study, patients with

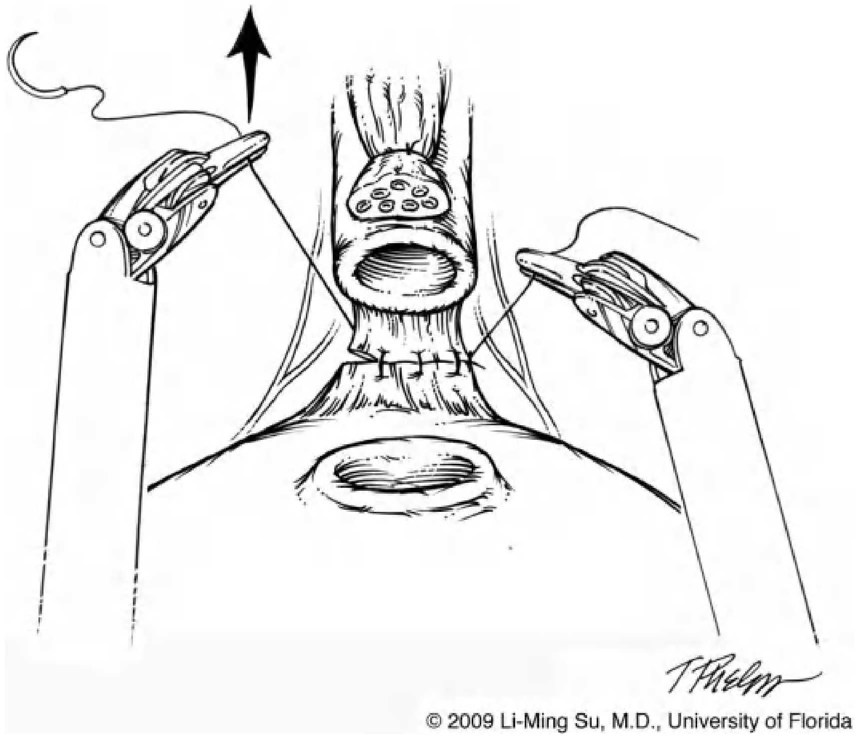

Figure 92.4 Modified Rocco stitch. The posterior rhabdosphincter, remnant Denonvilliers' fascia, and posterior detrusor layers are reapproximated with a running absorbable suture prior to the vesicourethral anastomosis.

intussuscepted bladder necks had significantly improved urinary control at 3 months (82% vs 54% in the control group, $P = .0035$) [45]. A second prospective study confirmed an earlier return to urinary continence at 3 months with intussusception of the bladder neck, though continence rates at 12 months were not significantly different when compared to the control group [46]. A modified version of Walsh's bladder neck reconstruction using just the anterior intussusception stitch has been described and incorporated into laparoscopic and robotic prostatectomy [47]. Further studies are necessary to evaluate the contribution of bladder neck intussusception to recovery of postprostatectomy continence following prostatectomy.

Early return of postprostatectomy continence has also been associated with cavernous nerve preservation [48, 49]. Wei *et al.* reported that median recovery time to complete continence was shorter after nerve-sparing prostatectomy (5.3 months vs 10.9 months, $P < .01$). They reported that while nerve preservation during prostatectomy may help retain autonomic and/or motor innervation to the rhabdosphincter, the surgical technique of sparing the NVB may also help decrease iatrogenic mechanical injury to the rhabdosphincter by avoiding unnecessary tension or traction [48]. Early continence rates after RALP have even shown improvement when comparing intrafascial versus interfascial nerve-sparing prostatectomy at 3 months (68.6% vs 27.3%, $P < 0.01$) and 6 months (68.8% vs 84.3%, $P < 0.01$), suggesting the possible importance of preserving the NVB in early recovery of postprostatectomy continence [22]. However, at 9 months there was no significant difference in continence rates between the groups in this study.

A novel and experimental concept recently described to improve postprostatectomy incontinence involves induction of hypothermia during nerve-sparing prostatectomy [50]. The idea behind induced hypothermia of the prostate bed is to reduce the inflammation and damage of surrounding neuromuscular tissues that may have a detrimental effect on urinary incontinence. This concept of hypothermia to reduce nerve injury caused by surgery or metabolic injury is not new and has been previously reported in the neurosurgical and cardiac literature [51]. Finley *et al*. incorporated the use of an endorectal cooling balloon system to their robotic prostatectomy to induce local hypothermia (mean of 26°C) to the prostatic bed. They reported a higher zero-pad continence rate with hypothermia at 3 and 12 months versus controls (89% and 100% vs 65% and 89%, $P < .0054$) [50]. While the effects of hypothermia on postoperative erectile function are still unknown and further studies are needed to validate the use of hypothermia, these and other concepts may lead to further

insights on how to maximize functional outcomes during radical prostatectomy.

Urinary continence rates after prostatectomy may also be improved with postoperative pelvic floor muscle rehabilitation. Postprostatectomy incontinence typically results from dysfunction of the urethral sphincter after striated muscle injury or damage to the innervating nerve fibers, though bladder dysfunction also likely contributes to postoperative incontinence. Pelvic floor muscle rehabilitation is intended to strengthen pelvic floor musculature that supports and closes the voluntary sphincter muscle and to facilitate improved bladder control. A recent updated report in the Cochrane Database of Systematic Reviews evaluated the role of pelvic floor exercises on the reduction of incontinence after radical prostatectomy [52]. There were seven randomized studies available for review; however, heterogeneity in the patient populations, study designs, therapeutic techniques, and definitions of continence precluded meta-analysis. The trials provided conflicting results and the Cochrane review could not conclude on a beneficial effect of pelvic floor exercises. The highest success rate reported for postprostatectomy pelvic floor rehabilitation showed that 88% of men were continent at 3 months versus 56% in the placebo group ($P < .001$) [53]. However, this is yet to be substantiated by further well-designed studies, which will be necessary to make definitive recommendations on the value of postoperative pelvic floor therapy.

Conclusions

The "trifecta" of cancer cure and complete preservation of urinary continence and potency represents the ultimate goal in radical prostatectomy. Unfortunately, achieving the "trifecta" occurs less than 100% of the time and cannot be achieved in all patients due to the extent of their disease, medical comorbidities, baseline characteristics, anatomy, and surgical technique. Technical advances have been made with LRP and RALP in efforts to optimize both oncologic and functional outcomes. However, in the end, it is important to counsel patients based upon their individual circumstances and clinical presentation, and provide realistic expectations in view of each individual surgeon's experience and outcomes.

CHAPTER 93

Minimally Invasive Simple Prostatectomy

Matthew H. Hayn & Khurshid A. Guru
Department of Urology, Roswell Park Cancer Institute, Buffalo, NY, USA

Introduction

Benign prostatic hyperplasia (BPH) affects approximately 70% of men aged over 70 years and is a significant cause of morbidity for those with BPH and a prostate weight of 60 g or more [1, 2]. The treatment options for bladder outlet obstruction (BOO) caused by BPH have expanded over the past two decades with the development of medical and minimally invasive therapies. For patients with acute urinary retention, persistent or recurrent urinary tract infection, refractory hematuria, severe urinary symptoms, or renal insufficiency, either transurethral resection of the prostate (TURP) or simple prostatectomy are indicated. In general, prostate glands larger than 70–100 g are better managed by open prostatectomy [3].

Open simple prostatectomy can be performed by a retropubic or suprapubic approach. The retropubic approach was popularized by Millin in 1945, and achieves enucleation of the prostate adenoma through a direct incision of the anterior prostatic capsule [4]. Suprapubic prostatectomy, or transvesical prostatectomy, consists of the enucleation of the hyperplastic adenoma through an extraperitoneal incision of the lower abdominal wall, and was popularized by Freyer in 1912, when he reported the results of his first 1000 patients [5].

As with many other urologic procedures, many centers have explored different techniques using a laparoscopic, and more recently, a robot-assisted and single-port approach. For many surgical indications, a robotic or laparoscopic approach translates into less postoperative pain, faster convalescence, fewer wound complications, and improved cosmesis. In 2002, Mariano *et al*. first reported using a laparoscopic approach for simple prostatectomy performed in a patient with BPH [6]. In that case report, a longitudinal vesicocapsular incision was performed to extract a 120-g prostate using four hemostatic sutures for vascular control [6]. Since that time, numerous other case reports and surgical series of laparoscopic simple prostatectomy have been reported [7–15]. Two series of robot-assisted simple prostatectomy have recently been published [16, 17], and single-site and single-port simple prostatectomies have also been reported [18–21].

Surgical techniques and outcomes (Table 93.1)

Laparoscopic prostatectomy

Since the first case of laparosopic prostatectomy was reported in 2002 [6], numerous other surgical series have been published. Most surgeons employ a retropubic (Millin's) approach, and both extraperitoneal and transperitoneal approaches are used. In addition, a finger-assisted technique is occasionally utilized [12, 15].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 93.1 Minimally invasive simple prostatectomy series.

Series	Approach	Cases	Mean EBL (mL)	Operative time (min)	Mean adenoma weight (g)	Hospital stay (days)	Number of conversions to open (%)
Laparoscopic							
van Velthoven *et al.* [8]	Retropubic	18	192	145	48	6	0

*Finger-assisted approach.
§Retropubic (n = 17) and transvesical (n = 13) approach.
†Five patients received index finger enucleation.
EBL, estimated blood loss.

In 2004, van Velthoven *et al.* reported on 19 patients who underwent laparoscopic extraperitoneal prostatectomy. Sotelo *et al.* reported their initial experience in 2005 on 17 patients who underwent laparoscopic retropubic simple prostatectomy: mean operative time of 156 min, estimated blood loss (EBL) of 516 mL, hospital stay of 2 days, and adenoma weight of 72 g (range 32–120 g). Three patients (19%) had postoperative complications [10]. In 2006, Mariano *et al*. followed up their initial case report by reporting on 60 patients who underwent laparoscopic simple prostatectomy. In their series, mean age was 69 years, surgical time was 138 min, EBL was 331 mL, and length of stay was 3 days. No patient required open conversion in their series [11]. They reported a significant improvement in maximum flow rate (Qmax) and International Prostate Score Symptoms (IPSS) [11]. Hoepffner *et al*. described a finger-assisted laparoscopic retropubic prostatectomy in 100 patients. At a mean follow-up of 14 months, all men had an IPSS score less than 5 and the mean Qmax was 26 mL/s. They advocated a finger-assisted approach over a pure laparoscopic approach given the shorter operative times and decreased wear on the laparoscopic instruments [15].

In 2009, McCullough *et al*. reported outcomes of 96 patients who underwent laparoscopic transcapsular simple finger-assisted prostatectomy as part of a comparative study with open simple prostatectomy. With their technique, an index finger is used to bluntly dissect the adenoma as in the open technique. The finger is inserted through the suprapubic trocar site [22]. Among the patients who underwent the laparoscopic approach, they reported a mean operative time of 95 min, EBL of 350 mL, and hospital stay of 6 days. Adenoma weight was not reported. Zhou *et al*. reported on 45 patients who underwent extraperitoneal laparoscopic retropubic prostatectomy, with five receiving index finger enucleation. They reported a mean EBL of 350 mL, surgical time of 105 min, postoperative stay of 6 days, and adenoma weight of 78 g (range 65–115 g) [12].

Robot assisted prostatectomy (Table 93.2)

The robotic system offers the surgeon several advantages over standard laparoscopy, including three-dimensional vision, six degrees of freedom in the instrument's movement, and downscaling of movements [3]. To date, two surgical series have been published on robot-assisted simple prostatectomy [16, 17]. At Roswell Park Cancer Institute (RPCI), we prefer to utilize the retropubic (Millin's) approach. The patient is placed in a steep Trendelenberg position and pneumoperitoneum is obtained via a Veress needle. A camera (12-mm) port is placed at the umbilicus with two robotic arm (8-mm) ports placed on the right and the left side. We place a right assistant side (12-mm) port in the right lower quadrant, a few centimeters above the anterior superior iliac spine. The fourth arm (8 mm) is placed on the left side and provides traction to aid with surgical

Table 93.2 Surgical steps for robot-assisted retropubic simple prostatectomy.

Surgical step	Lens	Right robotic instrument	Left robotic instrument	Fourth robotic arm	Assistant port
Incision of the peritoneum and entry into the space of Retzius	0° binocular lens	Hook cautery	Cardiere forceps	Cobra grasper	Microfrance grasper
Prostate capsulotomy	0° binocular lens	Hook cautery	Cardiere forceps	Cobra grasper	Suction
Dissection of adenoma	0° binocular lens	Hook cautery	Cardiere forceps	Cobra grasper	Suction
Apical dissection	0° binocular lens	Monopolar scissor	Cardiere forceps	Cobra grasper	Suction
Posterior mucosal advancement (3-0 Monocryl)	0° binocular lens	Needle driver	Needle driver	Cobra grasper	Laparoscopic scissor
Closure of the capsulotomy (2-0 Vicryl)	0° binocular lens	Needle driver	Needle driver	Cobra grasper	Laparoscopic scissor

exposure. A final 5-mm suction port is placed between the right robotic port and the camera port.

The posterior peritoneum is incised lateral to the umbilical ligament and the bladder is released from the anterior abdominal wall. The bladder is retracted using a grasper through the fourth arm. We make a transverse capsulotomy using electrocautery, and the adenoma is bluntly separated from the capsule using a grasper and the blunt side of the monopolar hook. Circumferential dissection is performed to free the adenoma from the prostatic capsule. We employ sharp dissection at the apex to avoid thermal injury to the external urethral sphincter. The prostatic fossa is then inspected and hemostatis is obtained. We approximate the posterior bladder neck mucosa to the posterior aspect of the prostatic capsule to prevent bladder neck contracture. After passing a urethral catheter into the bladder, the capsulotomy is closed transversely using a running 2-0 Vicryl suture. A suprapubic tube and/or JP drain can be placed at the surgeon's discretion.

Using this approach, we performed robot-assisted retropubic simple prostatectomy on three patients. The mean EBL was 558 mL, mean operative time was 211 min, and mean adenoma weight was 301 g (range 66–640 g). The mean hospital stay was 1 day, and one patient had a complication (bladder neck contracture at 4 months postoperatively) [16]. Limitations of robot-assisted retropubic prostatectomy are concerns for transperitoneal access and longer operative times. For patients with significantly enlarged prostates (>200 g), however, an extraperitoneal approach would prove to be challenging from a technical standpoint due to limited operative space. Not surprisingly, the patient in our series with the longest operative time and highest EBL had the largest adenoma weight (640 g) [16].

Sotelo *et al*. published a series of seven patients who underwent robot-assisted simple prostatectomy via a transperitoneal approach [17]. Their technique involved making a horizontal cystotomy incision proximal to the junction of the bladder and prostate, and performing the dissection of the prostate adenoma intravesically. In their series, the mean operative time was 195 min, mean EBL was 382 mL, mean hospital stay was 1.3 days, and mean specimen weight was 50 g (range 40–64.5 g). Four of their patients experienced postoperative urinary retention [17].

Single port prostatectomy

In 2008, Desai *et al*. first reported on three patients with BPH who underwent single-port transvesical enucleation of the prostate [18]. They later reported on 34 patients who underwent single-site transvesical enucleation of the prostate [21]. One procedure was done with robotic assistance. Nineteen cases (55%) were performed with finger assistance through the TriPort ring. They reported a mean operative time of 116 min (range 45–360 min), mean EBL of 460 mL (range 50–2500 mL), and mean hospital stay of 3 days (range 1–10 days). Four patients were converted to open, and eight patients experienced either an intraoperative or postoperative complication [21].

Comparative studies

There are several comparative studies between laparoscopic and open simple prostatectomy. Porpiglia *et al*. reported a prospective, nonrandomized study comparing open and laparoscopic extraperitoneal approaches for simple prostatectomy using the Millin's technique in

both groups (n = 20 in each group) [23]. They reported no difference in any preoperative parameter [age, prostate volume, prostate-specific antigen (PSA), IPSS score]. Patients who underwent laparoscopic prostatectomy had lower blood loss (412 mL vs 688 mL, $P = .004$). No difference was found in operative time, weight of adenoma removed, hospital stay, duration of catheterization, or postoperative complications [23]. Baumert *et al*. compared 30 patients who underwent laparoscopic simple prostatectomy with 30 prior patients who had undergone open simple prostatectomy [24]. Laparoscopic procedures were performed via a Millin's or transvesical technique (n = 17 and n = 13, respectively). They reported a longer operative time for the laparoscopic group, but lower blood loss, shorter irrigation time, shorter catheterization time, and shorter hospital stay. When comparing the laparoscopic Millin's versus laparoscopic transvesical approach, no difference was found between any of the perioperative parameters [24]. McCullough *et al*. compared 280 consecutive nonrandomized patients who underwent laparoscopy using the transcapsular finger-assisted or open transvesical prostatectomy (n = 96 and n = 184, respectively). The laparoscopic approach was associated with a longer operative time, shorter catheter duration, and shorter hospital stay. There was no difference in EBL between the cohorts [22].

Complications

Overall complication rates after minimally invasive simple prostatectomy ranged from 0% to 40%, although methods of reporting complications varied considerably [8, 10–12, 15, 22–24]. The majority of complications were considered minor, and no postoperative deaths were reported. In the comparative series, complication rates were similar between the open and laparoscopic approaches. Baumert *et al.* reported no difference in complications between the laparoscopic (n = 8, 27%) and open (n = 9, 30%) groups. Porpliglia *et al.* reported no difference in postoperative complications between the groups [23]. McCollough *et al*. did not report on overall complication rates between the open and laparosopic groups, but did report a higher rate of recatheterization fistula (3.1% vs 0%, $P = .039$) in the laparoscopic group. The open group, however, had a higher rate of urinary infection (9.8% vs 1%, $P = .012$) and urosepsis (4.9% vs 0%, $P = .030$) compared to the laparoscopic group [22].

In the single-port series from Desai *et al*., eight patients experienced a complication (23%) [21]. Three complications were intraoperative: enterotomy, bleeding requiring transurethral fulguration and transfusion, and bleeding in a Jehovah's Witness resulting in death. Postoperative complications included bleeding requiring transfusion (four patients) and urinary tract infection with epididymitis that responded to antibiotics and Foley catheter drainage [21]. Reported complication rates after robot-assisted simple prostatectomy were 14–33%. Specific complications were postoperative bladder neck contracture in one patient and epigastric artery injury necessitating blood transfusion in one patient [16, 17].

Conclusions

Laparoscopic, robot-assisted, and single-port simple prostatectomy are technically feasible and safe, and achieve comparable results to open simple prostatectomy. As centers of excellence gain further experience with these approaches, their roles in the management of symptomatic BPH will likely expand.

CHAPTER 94

Laparoscopic and Robotic Surgery of the Seminal Vesicles

James C. Brien & Michael D. Fabrizio
Eastern Virginia Medical School, Norfolk, VA, USA

Anatomy and physiology

Seminal vesicles are elongated saccular glands that develop from outgrowths of the mesonephric duct [1]. Located superior to the prostate and juxtaposed by bladder and rectum, the seminal vesicles are invested by Denonvilliers' fascia dorsally and the seminal vesicle fascia ventrally [2]. The seminal vesicles join the ampulla of the vas deferens to form the ejaculatory duct, which courses through the central zone of the prostate to terminate at the verumontanum [3]. Three distinct histologic layers are described: an inner layer of luminal epithelial cells, a middle layer of smooth muscle, and an outer layer of fibrous connective tissue, any of which may give rise to neoplasm [4]. The vesiculodeferential artery is the dominant blood supply to the seminal vesicle with lymphatic drainage primarily to the internal iliac nodes. Along with contributing a majority of the ejaculate volume, the seminal vesicles play a role in male fertility, secreting factors necessary for sperm motility, including fructose, prostaglandins, and coagulations factors [5].

Pathologic conditions

Pathologic lesions of the seminal vesicles are relatively infrequent and include neoplasm, seminal vesicle cysts, and infectious manifestations, including vesiculitis, abscess, and stones. Neoplasms of the seminal vesicles include benign as well as primary and secondary malignancies. Causes of obstruction of the seminal vesicles are variable and their description is beyond the scope of this chapter.

Infection and stones

Infectious manifestations are more common in countries where tuberculosis and schistosomiasis are endemic [6, 7]. Occasionally, removal of the seminal vesicles is necessary in patients with recurrent bacterial seminal vesiculitis not responsive to antibiotics. In immunocompromised patients or those with a recent history of instrumentation, infection may progress to abscess formation, often requiring intervention by surgical or percutaneous drainage. One potential complication of seminal vesicle infection or obstruction is stone formation [8]. Symptoms relating to seminal vesicle stones include chronic pelvic pain, hematospermia, and testicular/postejaculatory pain, and may require vesiculectomy or stone removal once diagnosis is confirmed [9, 10].

Seminal vesicle amyloidosis

Seminal vesicle amyloidosis is a local process distinguished from systemic amyloidosis by its immunohistochemical profile [11]. The most common presenting symptom is hematospermia, although clinical symptoms are rare [12]. Deposits of subepithelial amyloid are reported with variable frequency in older patients and therefore may be concomitant with other malignancies of the pelvis. As with other benign conditions, surgical removal is not necessary in asymptomatic patients.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Cysts

Seminal vesicle cysts are rare, occurring in less than 0.005% of the male population [13]. Cysts may be either congenital or acquired, are usually asymptomatic, and usually present after puberty [1]. The most frequently reported symptoms include pelvic pain, hematospermia, and urinary retention [14]. Differential diagnosis includes ureterocele, congenital vesicle diverticulum, or cyst of a mullerian remnant, urogenital sinus, ejaculatory duct or prostate [15, 16].

Congenital seminal vesicle cysts may be associated with ipsilateral renal abnormalities, such as renal agenesis/dysplasia [13, 17, 18], polycystic kidney disease [19], as well as ureteral ectopia and ureterocele [20]. This finding suggests a role for upper urinary tract imaging as part of the diagnostic work-up. Acquired cysts are thought to arise from ejaculatory duct obstruction relating to chronic prostatitis, benign prostatic enlargement, prostate surgery or malignancy [21]. Drainage or excision is necessary when associated with infection, compression of adjacent structures, infertility, malignancy degeneration or when cysts become symptomatic [22–25].

Retrovesicle hydatid cysts represent a rare pathologic process of the seminal vesicles resulting from echinococcal disease. This entity is usually accompanied by hydatid cysts in the liver [26]. Therapy involves pretreatment with albendazole followed by aspiration of cyst and injection of cyst cavity with hypertonic saline, hydrogen peroxide, and 10% formalin prior to vesiculectomy or removal of the cyst [27].

Neoplasms

Benign tumors

Papillary adenoma (cystadenoma) are benign mixed epithelial–stromal tumors that appear similar to seminal vesicle cysts on imaging. Criteria for diagnosis include localization of mass to the seminal vesicle without adjacent organ involvement, as well as absence of immunoreactivity to prostatic epithelial markers or carcinoembryonic antigen (CEA) [28, 29]. These lesions may be followed with transrectal ultrasound unless the lesion undergoes malignancy degeneration or becomes symptomatic [28].

Malignant tumors

The challenge with identification and treatment of malignant neoplasms of the seminal vesicle is distinguishing primary from secondary lesions. The frequency of seminal vesicle involvement by locally advanced tumors, such as adenocarcinoma of the prostate, far outweighs frequency of primary neoplasms [30]. Digital rectal exam, transrectal ultrasound imaging, cystoscopy, and sigmoidoscopy should be performed to rule out prostate, bladder, and rectal carcinoma [31]. Unfortunately, physical exam findings are often absent with no detectable abnormality noted on digital rectal examination or cystoscopic evaluation in 30% of patients diagnosed with seminal vesicle carcinoma [32, 33]. Normal serum prostate-specific antigen (PSA), prostatic acid phosphatase (PAP), and CEA suggest absence of secondary invasion by prostate or colonic carcinoma, while elevated CA-125 is strongly suggestive of primary seminal vesicle carcinoma [32, 34, 35].

Most malignant tumors arising from the seminal vesicle are adenocarcinoma. Although range of age at diagnosis is variable, most tumors occur in the sixth decade [31]. Clinical manifestations include hematuria, hematospermia, pelvic pain, dysuria, and urinary retention [31, 36]. Additionally, displacement of the trigone and ureteral obstruction may occur [34, 37]. Histopathologic diagnosis is usually made by transrectal ultrasound-guided needle biopsy, although in cases of bladder or prostate invasion transurethral resection may provide tissue diagnosis. Additionally, immunohistochemistry profile with positive CA-125, positive cytokeratin-7, and negative cytokeratin-20 can aid in differentiating seminal vesicle carcinoma from other pelvic tumors [31, 32, 35, 37]. Additionally, response to treatment may be monitored by following serum CA-125 levels [35].

Although initial reports demonstrated a poor prognosis, recent series have shown disease-free intervals of up to 50 months with organ-confined disease [36]. While there is no clear consensus on the extent of resection required in all patients, it is generally believed that tumor confined to the seminal vesicles may be removed by vesiculectomy if clear margins are accomplished [31]. If ejaculatory duct invasion is suspected, prostatovesiculectomy should be performed [38]. Aggressiveness of extirpation is directly related to suspected degree of local organ involvement.

Few cases of sarcoma of the seminal vesicles are reported, including leiomyoma, leiomyosarcoma, and fibrosarcoma [39]. Additionally, biphasic variants have been noted in the literature, including a cystic epithelial–stromal tumor and cystosarcoma phyllodes of the seminal vesicles [40, 41]. Radical extirpation is usually required due to aggressive behavior.

Examination findings

Signs and symptoms of seminal vesicle pathology are relatively vague and nonspecific. The most frequently reported symptoms include perineal or pelvic pain, painful ejaculation, urinary retention, irritative voiding

symptoms, infertility, and hematospermia. Because hematospermia is often self-limiting, work-up is not recommended unless in the presence of gross hematuria, infertility, or complaints relating to voiding or ejaculation.

Physical examination findings are limited. Occasionally masses, which may have either discrete or poorly defined margins, may be appreciated in the rectal examination. Cystoscopic findings within the bladder may reveal ipsilateral elevation of the trigone, distortion of the intertrigonal ridge, or no significant findings. Within the prostatic urethra, endoscopic findings include distortion of the verumontanum, patulous ejaculatory ducts or midline cysts [42]. Urinalysis findings may include microscopic hematuria, while semen analysis may reveal hematospermia, bacteria, or in the case of obstruction, low fructose levels.

Radiographic diagnosis

Transrectal ultrasound

Diagnosis of seminal vesicle disease often requires the assistance of radiographic imaging. Transrectal ultrasound (TRUS) is the most frequently used modality for imaging seminal vesicle pathology and is the initial study of choice. Seminal vesicles should be recognized as paired saccular organs just cephalad to the prostate with an echopenic center and echogenic vesicle walls [43]. Pathologic conditions demonstrated on TRUS include congenital cysts, which may be associated with renal aplasia or ureteral ectopia. These lesions appear as well-marginated anechoic masses contiguous with the seminal vesicle and in some instances, displacing adjacent structures [44]. Primary malignancies may be recognized as unilateral lesions, while secondary tumors are usually contiguous with the adjacent organ of primary tumor and frequently involve both seminal vesicles. No other imaging characteristics delineate benign from malignant tumors [45]. Biopsy or aspiration of lesions at the time of TRUS may be both therapeutic and diagnostic.

Computed tomography

Computed tomography (CT) allows imaging of the seminal vesicles, adjacent pelvic organs, and when necessary, the entire retroperitoneum. Seminal vesicles appear as paired organs caudal to the bladder with attenuation similar to that of soft tissue. Cysts are readily identified as well-defined, fluid-filled structures with Hounsfield unit characteristics of fluid (Figure 94.1), with the exception of hemorrhagic or infected cysts, which may show increased attenuation. Calcifications may be recognized in chronic infectious or inflammatory conditions, while long-term diabetes may demonstrate diffuse seminal vesicle calcifications [46]. Finally, CT cannot reliably distinguish benign from malignant or primary from secondary lesions. Unilateral lesions with intact tissue planes may suggest primary neoplasm. All solid or heterogenous appearing lesions require a histologic diagnosis.

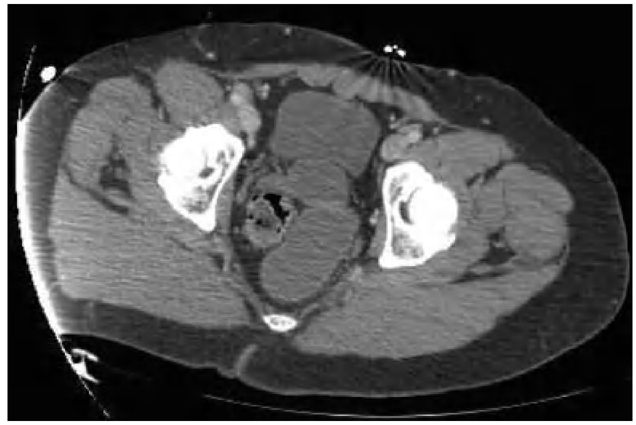

Figure 94.1 CT scan of patient with seminal vesicle cyst.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) provides anatomic information similar to that of CT, with the advantage of more precise delineation of tissue planes, which may improve preoperative staging of seminal vesicle tumors. Seminal vesicles appear to have low signal intensity on T1-weighted imaging and high intensity on T2-weighted imaging. Cysts have characteristic high intensity on T2-weighted imaging, which in hemorrhagic cysts may be accompanied by high T1-weighted imaging characteristics [44]. Diffuse wall thickening may be seen with both seminal vesiculitis and amyloidosis, and the latter demonstrates low T2-weighted and high T1-weighted imaging [47–49].

Although MRI cannot reliably distinguish between benign and malignant tumors, secondary neoplasms may be suggested by obliteration of adjacent tissue planes in the context of suspected malignancy. The most common secondary malignancy of the seminal vesicle is adenocarcinoma of the prostate. The sensitivity and specificity of MRI to detect seminal vesicle invasion by prostate cancer is 50–71% and 66–95%, respectively [50].

Surgery of the seminal vesicle

Minimally invasive surgical approaches

Open surgical approaches for treatment of seminal vesicle disease are variable, including retrovesicle,

transvesicle, transperineal, and transcoccygeal. Significant complications have been associated with open vesiculectomy, including rectal wall laceration, ureteral injury, and pelvic urinoma [45]. With increased experience with endoscopic, laparoscopic, and robotic techniques, most benign conditions and primary tumors of the seminal vesicles may be approached by minimally invasive techniques. The following section will focus on these treatment options.

Indications

Indications for operative intervention of seminal vesicle disease include presence of symptomatic seminal vesicle cyst, abscess, stone or chronic infection. Surgical extirpation of solid primary seminal vesicle masses is often indicated since imaging fails to differentiate benign from malignant neoplasms. Additionally, patients with seminal vesicle disease associated with an ectopic ureter and ipsilateral renal dysplasia may require extirpation, depending on the clinical scenario.

Prior to surgical intervention, patients may wish to cryopreserve sperm if both future fertility is desired and concern exists for intraoperative compromise of both ductal systems.

Endoscopic approaches

Endoscopic techniques for treatment of seminal vesicle conditions include treatment of ejaculatory duct obstruction, as well as seminal vesicle cysts or abscess in close juxtaposition to the prostatic urethra or bladder. Additionally, recent reports describe diagnostic and therapeutic endoscopic management of seminal vesicle stones.

Transurethral resection of the ejaculatory ducts (TURED) is offered to azoospermic men with suspected ejaculatory duct obstruction. Typically, the proximal verumontanum is resected in the midline using cutting current, after which fluid should be expressed from seminal vesicles to confirm patency. Resection should remain distal to the bladder neck and proximal to the external sphincter. In men with infertility secondary to congenital ejaculatory duct obstruction, improvements in semen parameters may be significant [47]. Patients must be aware of the potential risk of recurrent epididymitis secondary to reflux of urine as a result of the procedure.

Seminal vesicle cysts may be located in close proximity to either the trigone or prostatic urethra. Transurethral or transvesicle incision of the cyst using a Collins knife, electrocautery or a holmium laser has been demonstrated to provide adequate drainage and is generally considered effective and safe [48, 49]. Similarly, abscesses of the seminal vesicle have been drained transurethrally in a similar fashion with success [50].

Seminal vesicle stones may be accessed transurethrally by advancing a 6.9 F flexible or a 7 F semi-rigid ureteroscope into the utricular orifice and directing the scope into the seminal vesicle with or without guidewire assistance. Stones may be fragmented and extracted using conventional endoscopic manipulation. Interestingly, patients in two case reports undergoing treatment for seminal vesicle stones had both undergone prior TURED [10, 51].

While these methods report varied degrees of success, endoscopic treatments of seminal vesicle disorders appear largely to be temporary measures with a high incidence of pathology recurrence and infection [52–55]. Additionally, many of the open approaches for treatment of seminal vesicle disorders have been replaced with laparoscopic and robotic techniques. Laparoscopic magnification combined with the versatility of a 30° lens allow for superior visualization of the retrovesicle space compared to open approaches [56]. Finally, improved patient outcomes relating to decreased postoperative pain, lower patient morbidity, shorter hospital stay and earlier convalescence are reported with laparoscopic and robotic approaches [57, 58]. For this reason, treatment of most seminal vesicle pathology favors laparoscopic and robotic modalities when treatment is necessary.

Laparoscopic approach

The laparoscopic approach to the seminal vesicles was first described in 1993 by Kavoussi *et al.* [59]. Seminal vesicles may be accessed by transperitoneal or retroperitoneoscopic routes. Laparoscopic procedures vary from cyst decortication to vesiculectomy or prostatovesiculectomy.

The transperitoneal approach is similar for patients undergoing cyst decortication, seminal vesiculectomy or prostatovesiculectomy. Appropriate perioperative antibiotics and deep vein thrombosis prophylaxis are administered. After induction of anesthesia, arms are padded and tucked, and the patient is placed in steep Trendelenburg to facilitate bowel mobilization. Pneumoperitoneum is established via supraumbilical placement of a Veress needle. A 12-mm port is placed just above the umbilicus and the peritoneum is inspected with a 30° laparoscope. Two 5-mm ports are placed 9 cm inferolateral to the umbilical port toward the ipsilaral anterior superior iliac spine. A 12-mm port is placed 6 cm lateral to the right 5-mm port.

Adhesions are lysed and the sigmoid colon is mobilized out of the pelvis; we prefer a paddle retractor for bowel retraction. The peritoneum is incised in midline 3 cm above the junction of the bladder and rectum, and

opened transversely [9]. Seminal vesicles are usually easily identified in this location with a mixture of blunt and sharp dissection. In the event the seminal vesicles are not readily apparent, the ipsilateral vas should be identified at the external inguinal ring and traced medially. An incision can be made in the peritoneum medial to the right medial umbilical ligament over the vas. The right vas is traced towards the midline and the peritoneum is subsequently incised over the left vas toward the left medial umbilical ligament [56]. Once identified, the circumferential dissection of the seminal vesicle proceeds medial to lateral, and dissection is kept strictly adherent to the gland in order to avoid injury to the neurovascular bundle or adjacent structures, particularly the ureter located near the tip of the seminal vesicle [9, 58]. Denonvilliers' fascia is demonstrated posteriorly and separates the seminal vesicles from the rectum. As such, care should be taken to avoid excessive cautery in this area. The dominant artery is usually noted at the tip of the seminal vesicle. Clipping this vessel and dividing without cautery further marginalizes potential damage to adjacent nerves. The vas is clipped and divided and medially the ejaculatory duct is transected at the entrance to the prostate. The seminal vesicle is subsequently placed in an EndoCatch bag and extracted through one of the 12-mm ports. The surgeon may opt to plicate the prostate tissue adjacent to the divided ejaculatory duct with 3-0 Vicryl [20]. Most advocate reapproximating the peritoneum with absorbable suture and closure of the 12-mm ports with a 0 Vicryl suture.

In the case of symptomatic cysts in patients who wish to preserve fertility and sexual potency, decortication of the cyst may be performed if no concern for malignancy exists. In this instance the peritoneum overlying the cyst is incised transversely and the cyst is exposed [60]. Dissection of the most medial and lateral aspects of the seminal vesicle is avoided to prevent potential injury to the ejaculatory ducts and neurovascular bundle, respectively. The cyst is aspirated if necessary and decortication is performed by freeing the cyst from the posterior wall of the bladder, the anterior wall of the rectum, and the seminal vesicles laterally. Finally, the cyst is divided from its base with electrocautery, leaving a narrow strip of cyst wall on the vas [61].

Some authors advocate filling of the seminal vesicle cyst with contrast prior to removal via cannulation of the ipsilateral ejaculatory duct with a 3 F ureteral catheter to confirm the diagnosis. Additionally, filling of the cyst with dilute methylene blue to facilitate intraoperative demarcation of cyst margins has been described via cannulation of the ejaculatory duct with a small catheter. Alternatively, direct injection of the ipsilateral vas with methylene blue using a 25 G needle after mobilizing the vas through a small scrotal incision may be performed to facilitate cyst localization [60, 62].

Review of 12 case reports of laparoscopic seminal vesicle excision demonstrates total operative time ranging between 90 min and 364 min, with mean operative time of 183 min. Hospitalization varied from 1 to 5 days, with a 2-day average length of stay. No significant complications were documented [55–58, 60].

Retroperitoneal approach

Retroperitoneoscopic extirpation of the seminal vesicles is done in patients who require removal of the prostate. In short, a small incision is made near the umbilicus through which a balloon trocar is inserted. The balloon is inflated under direct vision to create the retroperitoneal space, after which the remaining trocars are placed and the retroperitoneal space is insufflated [45]. The dissection of the seminal vesicles follows transection of the bladder neck and incision of the ventral lamella of the seminal vesicle fascia.

Robotic approach

The da Vinci Surgical System™ (Intuitive Surgical Inc, Sunnyvale, CA, USA) provides a platform that facilitates performance of complex laparoscopic procedures by providing the surgeon with three-dimensional visualization, tremor reduction, ease of suturing, and increased degrees of freedom over traditional laparoscopy [62]. While the approach and dissection of the target tissue are essentially the same as they are for the laparoscopic approach described above, the decision to utilize the robot is based on surgeon preference. Operative times are comparable to those of seminal vesiculectomy performed laparoscopically [20, 63].

Trocar spacing is similar to that described in the previous section (Figure 94.2). We recommend use of a 0° lens and placement of the camera port no closer than 15 cm and no further than 19 cm from the pubic symphysis. In this instance, the 5-mm ports are replaced by 8-mm trocars. We place a third 8-mm port 6 cm lateral to the left 8-mm port and utilize the fourth robot arm for retraction of the bowel. We utilize monopolar scissors and bipolar Maryland forceps for dissection.

The cul-de sac is inspected and peritoneum overlying the seminal vesicles is incised (Figures 94.3 and 94.4). In the patient shown in these figures, future fertility was not a concern and we therefore used the vas for medial retraction (Figure 94.5). The circumferential dissection remains strictly adherent to the seminal vesicle (Figure 94.6). Control of vessels and removal proceed similarly to in the laparoscopic approach previously described.

Figure 94.6 Dissection of seminal vesicle.

Conclusions

A variety of seminal vesicle pathologies exist. Diagnosis often requires a combination of radiographic and histopathologic findings. Most conditions requiring surgical treatment may be approached using endoscopic, laparoscopic or robotic techniques.

CHAPTER 95

Laparoscopic Abdominal Wall Hernias: Incisional, Parastomal, and Inguinal Hernia Repairs

Thai T. Nguyen[1] & Howard N. Winfield[2]

[1]Advanced Urology Associates, Joliet, IL, USA

[2]West Alabama Urology Associates, Tuscaloosa, AL, USA

Abdominal wall incisional and parastomal hernias

Abdominal wall hernia following major genitourinary or abdominal surgery is a significant surgical problem. It has been reported that up to 26% of patients who undergo major abdominal surgery can develop an abdominal wall hernia [1–3]. Factors that may predispose a patient to the formation of such hernias include multiple abdominal surgeries, infection, obesity, poor nutritional status, and chronic medical problems, especially pulmonary, all of which interfere with the normal healing process.

Traditionally, the repair of abdominal wall hernias has been approached via an open technique. A wide variety of techniques have been developed, such as those described by Stoppa and Wantz [4, 5]. However, the recurrence rate after open suture incisional hernia repair has been reported to be as high as 54% [6, 7]. While the introduction of prosthetic material in incisional hernia repair has decreased the recurrence rates, the risk of wound infections and local wound complications may be increased [8–13]. Due to the high recurrence rates, and subsequent reattempts at repair followed by increasingly higher recurrence rates, an alternative to open surgery is attractive.

With the advent of laparoscopic surgery, a new form of hernia repair is now available to surgeons. The goal of the laparoscopic approach to abdominal hernia repair should be to decrease recurrence rates and wound complications, while offering the patient the advantages of a minimally invasive procedure. The first laparoscopic incisional hernia repair was reported in 1993 [14]. Since that time, studies comparing open and laparoscopic abdominal wall hernia repair have suggested that patients who undergo laparoscopic hernia repair experience the predicted advantages of less pain and shorter hospitalization, while the recurrence rate and complication rates are lower [15, 16].

Parastomal hernia following formation of an ileostomy or colostomy is not uncommon. This condition is associated with 1.8–28.3% of end ileostomies and 4–30.8% of end colostomies [17]. These rates are somewhat lower following loop ileostomies and colostomies. The site of stoma formation (through or lateral to the rectus abdominis), trephine size, fascial fixation, and closure of lateral space are not proven to affect the incidence of hernia. If repair is required, a prosthetic mesh technique should be considered, especially if the hernia is recurrent [17, 18] (Figure 95.1).

Indications

The laparoscopic approach may be considered for repair of any form of incisional abdominal, flank or parastomal hernia that may occur following genitourinary surgery. However, general recommendations are that if the hernia size is greater than 15 cm in transverse dimension, a laparoscopic approach may not be optimal and may be severely limited by the working space requirements. In this case an open approach such as myofascial rectus abdominis flaps (the separation of parts

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

technique) may be preferable for incisional hernias [19]. For very large parastomal hernias, an open approach with mesh and/or relocation of the stoma may be preferred. Mesh should be generally avoided in the presence of suspected infection or a history of radiation. Comorbidities such as obesity, peripheral vascular or heart disease may favor the laparoscopic approach as the speed of the procedure, lack of significant third spacing of fluids, avoidance of significant ileus, and decreased pain all help the more ill patient with a symptomatic hernia [19].

Patient preparation

All patients undergo preoperative imaging by computed tomography (CT) scan, with a concurrent loopogram performed in the case of parastomal hernias, to determine the contents of the hernia and define the extent of the fascial defect (Figure 95.2). All patients receive oral antibiotics and a full mechanical bowel preparation with Golytely®, and are typed and screened for blood products. Patients are routinely given one dose of broad-spectrum antibiotics on call to the operating room.

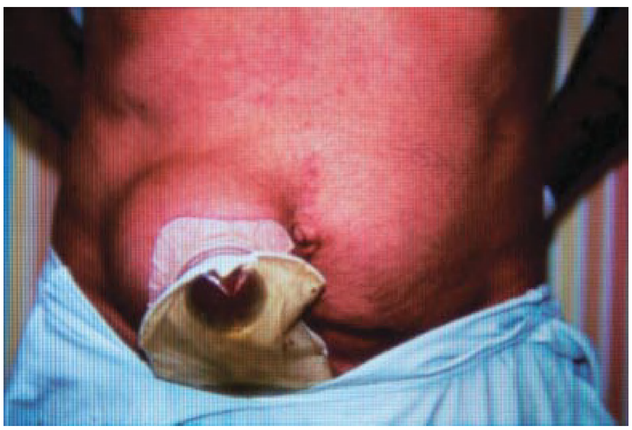

Figure 95.1 Parastomal hernia following ileal conduit formation.

Surgical technique

Prior to performing the laparoscopic repair, an orogastric tube is placed for gastric decompression and a 16F Foley catheter is placed in the bladder or stoma of the urinary diversion in the case of a parastomal hernia repair.

Under general anesthesia, the Hasson cannula technique is used to obtain an initial pneumoperitoneum. The location of the initial entry port is at a site farthest away from the hernia defect and surgical incision, so as to minimize the risk of entry into an area of adhesions or bowel. In other words, if the hernia were in the right mid/lower abdomen, the Hasson cannula entry would be at the left upper quadrant. The working port size, number, and placement are dependent on the location, type, and size of the hernia. Generally three to four ports (5–11 mm) are required. The basic objective is to space out the ports in a triangular fan-shape configuration with the apex of the triangle directed to the hernia. Adhesiolysis is achieved with both blunt and sharp dissection. The hernia contents are emptied and the fascial edges are freed circumferentially of overlying tissue beyond 3 cm (Figure 95.3). The mesentery supplying the ileal or colonic conduit is carefully identified and preserved, with separation from surrounding herniated bowel in the case of parastomal hernia repairs (Figure 95.4).

The circumferential dimensions of the hernia defect are measured by percutaneously placing an 18G spinal needle under laparoscopic guidance through the edge of the fascial defect. Once the size of the defect is determined, a piece of polytetrafluoroethylene Gore-Tex®

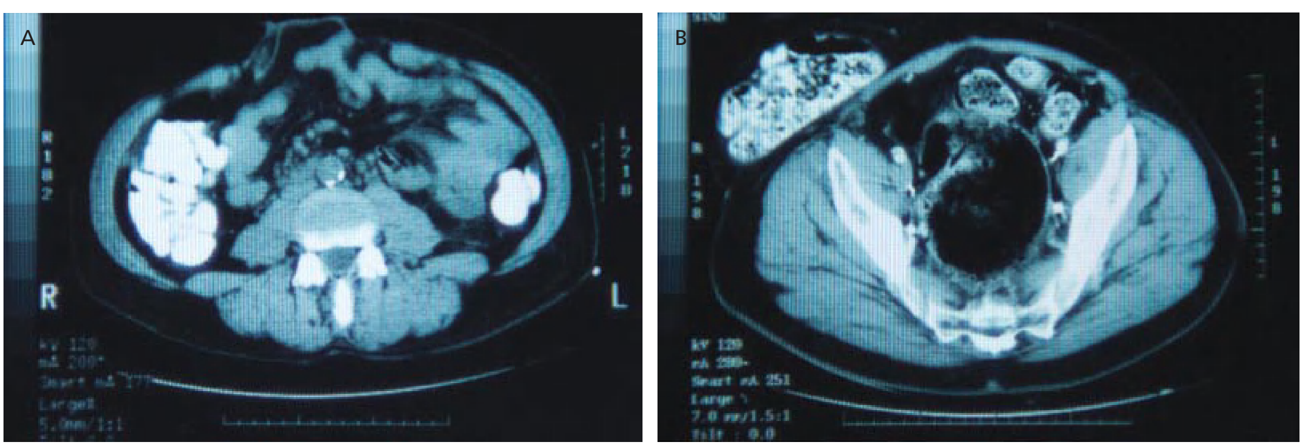

Figure 95.2 (A, B) Incisional hernia following radical cystectomy.

DualMesh product (W.L. Gore & Associates, Flagstaff, AZ, USA) is cut 2–4 cm larger. Four quadrant stitches of 2-0 Gore-Tex® are placed on the mesh, which is then rolled up and inserted into the abdominal cavity through a 10/11-mm port site. The DualMesh has a smooth side with a pore size of less than 3 μm, which diminishes adhesion formation to bowel, and a rough side with a pore size of 22 μm, which allows more ingrowth of fibroblast and collagen. The smooth side is oriented towards the bowel contents and the rough side towards the abdominal wall. The mesh is positioned and the quadrant stitches brought out percutaneously using the Carter Tomlinson® device (Inlet Medical, Eden Prairie, MN, USA). The helicoidal staples (ProTack®; Autosuture Inc, Norwalk, CT, USA) secure the Gore-Tex® mesh to the fascia edge beyond the defect. Tacks are placed every 1.5 cm around the outer edge of the defect. In the case of a parastomal hernia, a radial incision is made in the Gore-Tex® mesh such that the wings can be wrapped behind the stomal loop of bowel and secured in place (Figure 95.5). We have found it easiest to fashion the radial incision within the abdominal cavity after the mesh has been partially secured, rather than trying to anticipate the location *ex vivo*. Final hemostasis is obtained and the port sites are closed in the usual fashion.

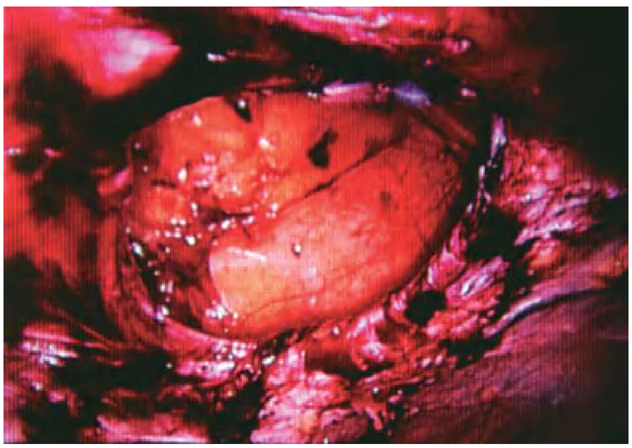

Figure 95.3 Intraperitoneal borders of incisional hernia defined.

Postoperative care

An abdominal wall compressive dressing is placed at the termination of the procedure so as to reduce the development of postoperative seromas, and the patient is encouraged to wear an abdominal wall binder as much as possible over the ensuing 6 weeks. Discharge from hospital is variable but usually occurs within 1–3 days, depending on the size of the hernia repair, postoperative pain, and resolution of any adynamic ileus. Strenuous or lifting activities are discouraged for 6 weeks.

Results

Laparoscopic incisional hernia repair has gained increasing popularity as a result of the low recurrence and complication rate of the procedure, as well as improved patient postoperative course. Table 95.1 lists some recent studies of laparoscopic incisional hernia repair [20–26]. Most surgeons are using expanded polytetrafluoroethylene (PTFE) in their repairs. The recurrence rates appears to be 2–4%, but has been reported as high as 9% depending on the study and the surgeons' experience. Mean follow-up is reasonable at 22.5 months. The most

frequent complications with laparoscopic incisional hernia repair are unresolving seromas (1–36%), wound infections (0–6%), ileus (1–10%), bowel injury (0–6%), and prolonged pain (0–2%) [27].

Finally, four studies comparing laparoscopic mesh and open mesh incisional hernia repair suggest that the recurrence, complication, and hospitalization rates are lower with the laparoscopic approach (Table 95.2) [15, 28–30]. However, only one of these clinical studies is randomized [28].

Sizeable studies of laparoscopic parastomal hernias are currently unavailable in the literature. Most studies consist of case reports or small series. Our own study consists of four patients who have all done well with the

use of DualMesh at greater than 12 months follow-up [31]. There have been no complications or recurrences noted in this small series.

The most dangerous and time-consuming part of the procedure is the lysis of bowel and omental adhesions from the abdominal wall, and the reduction of the hernia contents. Adhesiolysis should be performed with judicious use of electrocautery or the Harmonic shears (Ethicon Endo-surgery, Cincinnati, OH, USA), especially in close proximity to the bowel. Careful inspection of the abdominal cavity after placement of the mesh for bleeding or bowel injury is mandatory. In the event of an iatrogenic enterotomy, the original standard of care is repair of the injury by laparoscopic means or laparotomy and removal of the mesh. Placement of the mesh (i.e. foreign body) in this situation is discouraged. Some authors, however, have reported placing the mesh laparoscopically in the face of only an isolated bowel injury in patients who have undergone a very thorough bowel preparation, who have no other risk factors such as steroids, and in whom the injury is recognized immediately and spillage has not occurred [32].

In the presence of potentially contaminated abdominal wall defects, the use of Surgisis (Cook Surgical, Bloomington, IN, USA), a four-ply bioactive, prosthetic mesh derived from porcine small-intestine submucosa, might be considered [33].

Of the currently available prosthetic materials, Gore-Tex® mesh has been shown to have the lowest foreign body reaction, rate of adhesion formation, and infection rate [34, 35]. An alternative popular material is the Composix® E/X mesh (Davol Inc, Cranston, RI, USA).

Laparoscopic inguinal herniorrhaphy

Schlegel and Walsh reported that inguinal hernias may be present in 5–12% of men with clinical prostate cancer [36]. In the urologic community, these authors popularized the transabdominal preperitoneal repair of inguinal and femoral hernias at the time of pelvic surgery. Subsequent reports confirmed the usefulness of preperitoneal herniorrhaphy concurrent with urologic procedures in both children and adults [37–39]. With the explosion of interest in laparoscopy- and robot-assisted radical prostatectomy, and given that one in 10 men undergoing laparoscopic pelvic lymphadenectomy or prostatectomy might have an inguinal hernia, proficiency in laparoscopic herniorrhaphy would obviate the need for reoperation under a second anesthetic, minimize morbidity for the patient, and reduce overall costs to the healthcare system.

As advances in technology and refinements in techniques improve the outcomes of laparoscopic inguinal hernia repair, the procedure will be performed more often. In the future, urologists will encounter more and more patients who have undergone such repairs. Indeed, there have been reports of laparoscopic inguinal herniorrhaphy complicating subsequent radical retropubic prostatectomy, even forcing the procedure to be aborted in some cases [40–42]. It would therefore benefit any urologist to be familiar with laparoscopic inguinal herniorrhaphy.

Indications

Laparoscopic inguinal herniorrhaphy may be performed for direct or indirect defects, including primary, recurrent, and bilateral inguinal hernias, as well as for femoral hernias.

Patient preparation

Preoperative studies

For the patient for whom laparoscopic urologic surgery is planned, careful examination of the inguinal region with the patient in the upright position during a Valsalva maneuver may reveal the presence of an otherwise asymptomatic hernia. As for all laparoscopic surgery, routine blood work and radiologic imaging is obtained based on the patient's age and medical history. Even if the urinalysis is not suggestive of infection, a urine culture is recommended to exclude this avoidable source of prosthetic infection, especially if the hernia repair is to be done concurrently with a urologic procedure that allows urine into the surgical field (i.e. radical prostatectomy).

Medications

All anticoagulants, nonsteroidal anti-inflammatory agents, and Aspirin-containing products are discontinued for 7 days preoperatively. Bowel preparation is administered at the discretion of the surgeon. Intravenous broad-spectrum antibiotics, while not strictly required in a "clean" surgical case, are prudent when prosthetic material is to be implanted.

Informed consent

Assuming that the patient is to undergo laparoscopic herniorrhaphy concurrently with another laparoscopic procedure, a discussion of the risks and benefits of laparoscopy in general should have already taken place. Potential complications specific to laparoscopic inguinal hernia repair are discussed later. The patient is advised that the primary urologic procedure takes precedence; if laparoscopic herniorrhaphy at the conclusion of the procedure does not appear likely to proceed uneventfully due to a difficult previous dissection in the pelvis,

bleeding, anesthetic considerations, or other reasons, then it may be postponed. The patient is preoperatively given the option of an open hernia repair under the same anesthetic if the urologist decides against the laparoscopic approach intraoperatively.

Positioning of equipment and personnel

The main video monitor, insufflator, video unit, light source, and electrosurgical generator are located on a movable cart placed at the foot of the operating table, thereby allowing the surgeon an unobstructed view of the monitor and instrument indicators.

Patient positioning

The patient is placed supine in a moderate head-down tilt with the ipsilateral side rotated upward. Arms should be tucked by the side so that they do not impede the movement of the primary surgeon. A Foley catheter should be placed to drain the bladder and an orogastric tube placed to decompress the stomach.

Inguinal–pelvic anatomy

The key to successful and safe laparoscopic herniorrhaphy is a thorough understanding of the inguinal–pelvic anatomy. Urologists familiar with laparoscopic pelvic surgery are experienced in identifying these structures from a laparoscopic perspective. A brief review will nonetheless facilitate subsequent explanation of the procedural steps.

The first landmarks evident from the intraperitoneal perspective are the three umbilical ligaments, all formed by peritoneal folds overlying preperitoneal tubular structures. The median umbilical ligament, over the obliterated urachus, is directly in the midline extending from the dome of the bladder to the umbilicus. The medial umbilical ligaments, representing the obliterated umbilical arteries, are usually the most prominent structures, but may be obscured by preperitoneal fat in some patients. They are oriented in an inverted V shape, running from the deep pelvic space medial to the external iliac vessels and lateral to the bladder up along the anterior abdominal wall toward the midline. All dissection for unilateral laparoscopic herniorrhaphy is performed lateral to the medial umbilical ligaments. Between the medial and inferior epigastric vessels lies the medial fossa, where direct inguinal hernias occur. The lateral fossa is just lateral to the inferior epigastric vessels, wherein lies the internal inguinal ring, the site of indirect inguinal hernias.

Within the preperitoneal space lie the structures responsible for creating the umbilical ligaments: the urachus, umbilical arteries, and inferior epigastric vessels. Other pelvic structures in this space are the vas deferens, external iliac vessels, the deep circumflex iliac vessels, and pubic or accessory branches of the inferior epigastric vessels. The courses of these arteries and veins are best understood in terms of their relationship to the transversalis fascia analogs (the iliopubic tract, Cooper's ligament, and iliopectineal arch), which are the thickenings and condensations of the transversalis fascia that define the layer external to the preperitoneal space. Whereas the inguinal ligament is the landmark often used by inguinal surgeons, the best landmark for the laparoscopist performing herniorrhaphy is the iliopubic tract. This strong fascia runs from the iliac crest and anterior superior iliac spine inferiorly and medially to curve around the femoral sheath and attach to Cooper's ligament and the pubic tubercle. It forms the medial border of the internal inguinal ring and the lateral border of the femoral ring (Figures 95.6 and 95.7). Cooper's ligament is seen by the laparoscopist as the white ligament coursing back from the pubic ramus under the distal portion of the external iliac vessels to lie at the inferomedial border of the femoral ring. The iliopectineal arch and the underlying aponeurotic arch of the transversus abdominis run lateral to the iliopubic tract, forming the lateral border of the internal inguinal ring, and then insert along with the iliopubic tract on the pubis and Cooper's ligament. The triangular space created by the iliopubic tract and aponeurotic arch inferior (distal) to the inferior epigastric vessels and internal inguinal ring is the weak point in the medial fossa through which direct herniation occurs. An indirect hernia is seen laparoscopically as an orifice lateral and superior to the inferior epigastric vessels (Figure 95.7).

The testicular vessels laterally and the vas deferens medially form the "triangle of doom" for the novice surgeon performing laparoscopic herniorrhaphy (Figure 95.7). This triangle containing the proximal portion of the external iliac vessels is the area where the urologist performs laparoscopic pelvic lymphadenectomy. Deep dissection in this area during laparoscopic herniorrhaphy is unnecessary and risks vascular injury. To avoid neurovascular injury during laparoscopic herniorrhaphy, however, the "triangle of doom" is an inadequate warning zone. The area just lateral to the testicular vessels or medial to the iliopubic tract contains nerves (femoral nerve, lateral femoral cutaneous nerve, and femoral branch of the genitofemoral nerve) and vessels (deep circumflex) that lie just external to the transversalis fascia [43]. When fixing the prosthesis in place, it is unnecessary and unsafe to place staples medial to the iliopubic tract in the area superior and lateral to the inguinal ring. The inferior epigastric vessels, distal portion of the external iliac vessels, and their pubic or accessory obturator branches all lie within areas that must be approached when properly stapling the

prosthesis to the anterior abdominal wall and Cooper's ligament. Close inspection of all sites before stapling is essential.

Surgical options

Five major types of laparoscopic herniorrhaphy have been described: closure of the internal ring without prosthesis, plug repairs, intraperitoneal onlay mesh (IPOM), transabdominal peritoneal repair (TAPP), and totally extraperitoneal repair (TEP). Currently, only TAPP and TEP are commonly used.

The first laparoscopic hernia repair, performed by closing the internal inguinal ring with clips to treat an indirect hernia, was reported by Ger in 1982 [44], with a later report published in 1990 [45]. Simple suture

closure of an indirect hernia defect and reapproximation of the peritoneum over the repair with clips was subsequently reported by others [46, 47]. These repairs were applicable only to indirect hernias and subsequently abandoned due to unacceptably high early recurrence rates.

The next development in laparoscopic inguinal herniorrhaphy was reported in 1989 by Bogojavlensky who placed a roll of polypropylene mesh into indirect and femoral hernia defects and closed the peritoneum over the defect [48]. Excision of the hernia sac prior to plugging of the defect with mesh was reported by Schultz *et al.* in 1990 [49]. Several other modifications to plug repairs have been described, including the application of a patch over the proximal end of the plug over which the neck of the inverted hernia sac was stapled [50], formation of the plug into a fan [51] or mushroom shape [52], attaching the patch to the plug prior to implantation [53], and suturing the aponeurotic arch to the iliopubic tract over the plugged defect [54]. Although the patch is sewn or stapled to transversalis fascia analogs in several of these repairs to improve fixation [54–56], methods incorporating a prosthetic plug have been abandoned because of high recurrence rates and migration of the plug into the inguinal canal, mimicking recurrence [43].

The remaining three techniques of laparoscopic hernia repair are based on the open preperitoneal prosthetic repair of Stoppa. The first of these techniques, the IPOM repair, was reported in 1990 when Popp described the laparoscopic suturing of the margins of a direct inguinal hernia followed by the intraperitoneal placement of a patch of dehydrated dura mater [57]. Subsequent techniques have involved the intraperitoneal fixation of a nonabsorbable prosthesis over the hernia defect [58–63]. Despite the minimal dissection required and associated decreased operative time, interest in this technique has been limited by concerns of possible adhesion formation or erosion of mesh into the abdominal viscera [43].

Currently, a popular approach to laparoscopic herniorrhaphy is TAPP. Through an intraperitoneal approach, the peritoneum is widely incised and reflected to expose the transversalis fascia analogs supporting the inguinal area. A large patch of prosthetic material is then placed overlying the medial and lateral fossae with generous overlap. The mesh is usually stapled in place, taking care to avoid nerve entrapment, after which the peritoneum is closed. The first large series describing this standard technique was reported by Arregui *et al.* [64] in 1992, and numerous publications since then attest to its popularity. The advantage of TAPP over IPOM is that the peritoneum is interposed between the abdominal contents and the prosthesis, diminishing adhesion formation [65] and presumably the risk of viscera erosion.

TEP is based on the same anatomic principles as TAPP but attempts to avoid the potential complications of transperitoneal laparoscopy. Although Popp in 1991 proposed the use of percutaneous aquadissection to help develop the preperitoneal space prior to insertion of a prosthesis transabdominally [66], McKernan and Laws [67] and Ferzli *et al.* [68] in 1992 first described a totally extraperitoneal approach in the literature. Some have reported visualizing the inguinal site from the intraperitoneal perspective while inserting and then fixing the prosthesis extraperitoneally [69, 70], while others perform the entire procedure in the extraperitoneal space [67, 68, 71–73]. The extraperitoneal space can be developed with a balloon dissector [71, 73], fluid [70], or gas [67–70, 72], with or without the use of a blunt probe [67–69, 72] to aid in the dissection. The proponents of TEP argue that the risk of intraperitoneal complications is reduced compared to the transperitoneal approach [74]. Difficulties with TEP include a limited working space and indistinct anatomic structures. The learning curve for the strictly extraperitoneal approach may be longer than for other techniques. Urologists who perform extraperitoneal laparoscopic radical prostatectomy, however, will be experienced with this approach.

Transabdominal preperitoneal herniorrhaphy

A skin incision is made at the inferior crease of the umbilicus, and pneumoperitoneum is created with a Veress needle, following which a 10–12-mm port is inserted. Alternatively, access can be obtained via the Hasson technique in the same location. After inspecting the abdominal cavity with a 10-mm, 30° laparoscope, two secondary ports are inserted, one on each side of the patient a few centimeters below the level of the umbilicus in the anterior axillary line. To facilitate insertion of the mesh, one port should be 10–12 mm in size, while the other can be 5 mm in size. Alternate port configurations include replacing the contralateral port with one in the midline half the distance between the umbilicus and pubis, or placing the lateral secondary ports lower in the abdomen.

The peritoneum is incised transversely across the anterior margin of the hernia defect(s) from the medial umbilical ligament to the anterior superior iliac spine. Care is taken to keep the incision horizontal and to not allow it to drift anteriorly. This incision will place the hernia approximately in the middle of the operative field and will allow subsequent exposure of the transversalis fascia analogs (Figure 95.8). The only significant structures crossed by the incision are the inferior epigastric vessels and the iliopubic tract. Injury to the former usually can be avoided with careful dissection. Although not necessary in most instances, these vessels can be

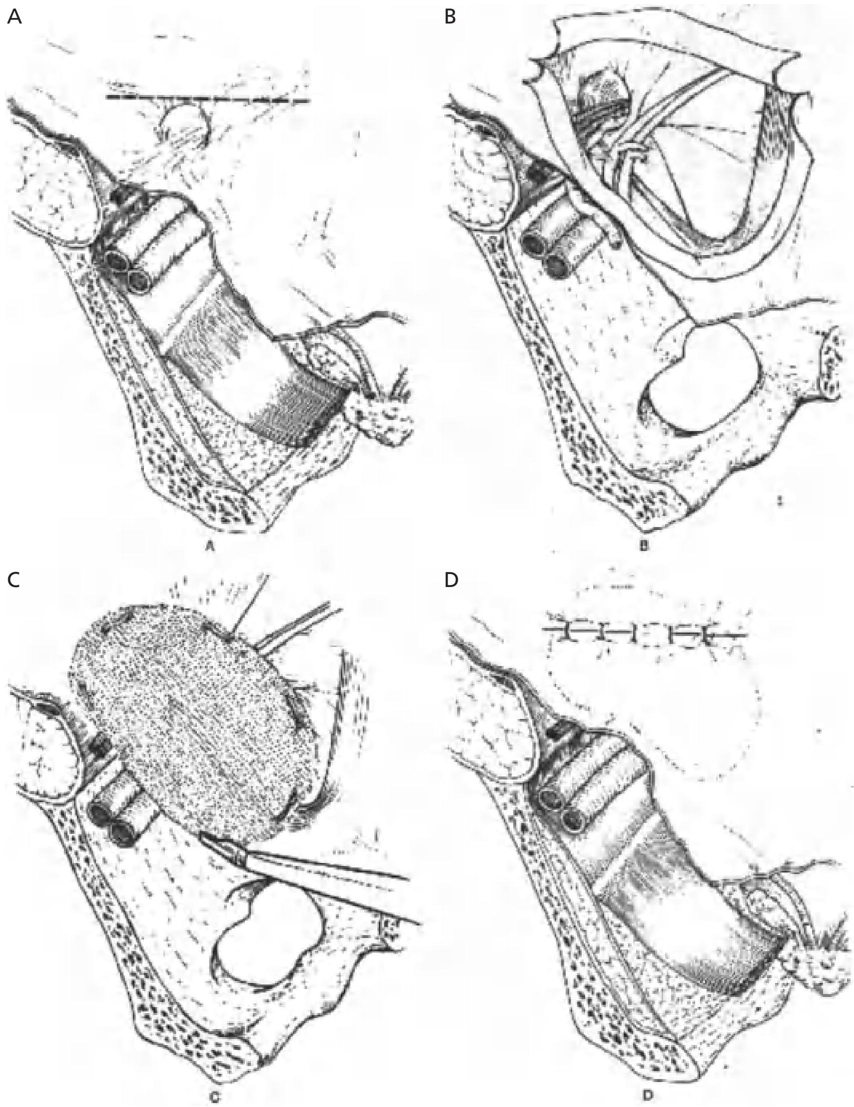

Figure 95.8 Steps in laparoscopic transabdominal preperitoneal repair of the left inguinal hernia: (A) the peritoneum is incised transversely over the hernia defect (dotted line), (B) peritoneal flaps are reflected to expose the inguinal floor, (C) the prosthetic mesh is stapled into place, and (D) the peritoneum is closed over the mesh (reproduced from Soper, N.J., Brunt, L.M., Kerbl, K. Laparoscopic general surgery. *N Engl J Med* 1994;330:409–419, with permission).

clipped and transected if troublesome. The iliopubic tract serves as an important landmark for staple placement later in the procedure.

Retracting the peritoneal edges and bluntly dissecting them free from the body wall and underlying structures develops the peritoneal flaps. If adherent areas are encountered, the surgeon can either use retraction and counter-traction by grasping the adherent band of tissue with a second instrument and separating the structures, or the band, if it is judged not to be vascular, may be transected. The vas deferens must be identified and preserved during these maneuvers if it has not already been divided during laparoscopic pelvic lymphadenectomy or radical prostatectomy. The posterior peritoneal flap is developed first. The posterior limit of the dissection is Cooper's ligament inferomedially. Superolaterally, the flap should be reflected only as far as the iliopectineal arch and testicular vessels. Next, the anterior half of the peritoneal flap is reflected. The only structures at risk of injury here are the inferior epigastric vessels, which should be left on the anterior abdominal wall. The flap should be reflected only 3–4 cm above the peritoneal incision.

A direct hernia sac, unless recurrent after a failed inguinal repair or particularly large, usually is reducible. An indirect sac is more frequently narrow and deep. If not reducible, the sac should be incised in a circumferential fashion just at or inside the neck of the sac. A

wide incision might compromise later closure of the peritoneum. Dissection and attempted removal of the amputated sac are unnecessary and pose a risk of neurovascular injury. The retained sac may fill with fluid postoperatively (groin seroma or scrotal hydrocele), but the collection usually resolves within a few weeks without sequelae. The preperitoneal area that has been exposed is next cleared of fatty tissue, with special attention paid to Cooper's ligament and the iliopubic tract, which will serve as the main anchoring points of the prosthesis. Small vessels, branches of the inferior epigastric or external iliac vessels, will often be seen crossing near Cooper's ligament. These should be avoided if possible, since they may retract under the tension of the pneumoperitoneum and result in hemorrhage during attempted ligation.

The prosthetic material (usually polypropylene) is now introduced into the abdomen through one of the larger ports. A 7 × 12-cm section usually is adequate to generously cover indirect, direct, and femoral hernia sites, but the surgeon should not hesitate to use a larger piece or even two separate pieces if additional coverage is required. The mesh is inserted by rolling or folding it so that it can be passed down the port with a fine-tipped curved dissector. Once in the peritoneal cavity, the mesh is unfurled and manipulated into the preperitoneal space. A third instrument port can sometimes be useful since it can be frustratingly awkward at times to get the prosthesis into the proper position. Some surgeons incise the mesh on one side so that it can slip around the spermatic cord. Others believe that this is unnecessary and place the prosthesis over the cord.

The 5-mm hernia stapler, or tacker, is inserted through the midline or contralateral port and used to fixate the anterior edge of the prosthesis first, avoiding the epigastric vessels. A bimanual technique using the nonoperating hand to palpate the head of the stapler through the abdominal wall facilitates exact placement. Applied pressure must not be too firm or tacks will penetrate too deeply, risking nerve entrapment. Another trick is to partially deploy the tack and use one end to "hook" the mesh and then guide it into place. The superolateral tacks are placed next, extending from the upper corner of the prosthesis only as far down as the iliopubic tract. The last tack(s), placed in the iliopubic tract itself, must not be placed too deeply lest nerves become entrapped. Tacks should not be placed medial to the iliopubic tract in this location for the same reason. When applying tacks lateral to the internal ring, the surgeon must be able to palpate the stapler head through the abdominal wall to ensure that tacks are not placed posterior to the inguinal ligament. Inferomedially, tacks are placed from the corner of the prosthesis down to the pubic tubercle and Cooper's ligament. Exact visualization of the deployment of each tack also is imperative to avoid injury to vessels coursing above, below, and over Cooper's ligament and the iliopubic tract. Finally, tacks are placed in the iliopubic tract running between the inferior edge of the prosthesis and the internal inguinal ring. Again, inexact or excessively deep tack placement risks neurovascular injury.

Although fixation of the mesh is usually included as an integral step in descriptions of laparoscopic inguinal herniorrhaphy, the necessity of this step is controversial. Many surgeons feel that fixation is crucial to reducing hernia recurrence by preventing the mesh from rolling up and uncovering the hernia defect. Mesh fixation, on the other hand, has been linked to an increased incidence of nerve injury and incurs the increased cost of the tacking device (or increased costs associated with longer operative times if fixation is accomplished by suturing). Recent retrospective studies as well as prospective, randomized trials have reported no significant differences in operative time, nerve entrapment, complications, or recurrences between fixed and unfixed mesh repairs [75–77].

The intra-abdominal pressure is decreased to inspect for hemorrhage and reduce tension on the peritoneum. The peritoneal incision and any defects created during reflection of the peritoneum or incision of the hernia sac are closed over the prosthesis either with the stapler or by suturing. The staples or sutures must be placed sufficiently close together to prohibit internal herniation through the peritoneotomy.

The port sites are inspected for bleeding from the inner aspect of the abdominal wall. Ports are removed one by one under vision at 5 mmHg intra-abdominal pressure and the gas is then evacuated from the abdomen. The 5-mm skin incisions are closed with subcuticular absorbable sutures and/or sterile skin tape. The larger incisions are closed with fascial sutures, followed by skin closure.

Totally extraperitoneal herniorrhaphy

TEP starts with a small infraumbilical incision that is carried down through the anterior rectus sheath to expose the rectus muscles. The muscles are split in the midline, and gentle finger dissection creates a tunnel down toward the pubis. Inferior to the arcuate line, this tunnel becomes the preperitoneal space. Choices at this stage are to insert a Hasson-type cannula and to start insufflating with gas to open up the preperitoneal space, to dissect with a blunt probe placed through an operating laparoscope, or to use a dilating balloon to gradually lift the peritoneum off the body wall and expand the preperitoneal space. This mechanical expansion breaks strands of connective tissue that often persist when gas alone is used and will prevent full expansion of the preperitoneal space, requiring tedious dissection to

transect them and allow complete visualization of the preperitoneal space. The simplest and least expensive dilating balloon is made on the operating table by tying the middle finger of a large sterile surgical glove over the end of a 16 F red rubber catheter or other available sterile tubing. Slow inflation of the balloon with approximately 1 L of saline or gas from the insufflator will safely expand the space to adequate dimensions. Alternatively, a commercially prepared dilating balloon can be purchased from one of several manufacturers. One advantage of some of the commonly available devices, the ability to look through and direct the balloon as it dilates, can be duplicated as well by the surgeon at the operating table by tying the finger of the glove over a long 10-mm laparoscopic cannula instead of a catheter. The balloon–cannula is inserted into the tunnel beneath the rectus muscles and the insufflator is connected. When the laparoscope is inserted into the balloon–cannula and the gas insufflated, the pelvic structures can be visualized through the balloon (albeit not too clearly). A final option for creation of the preperitoneal space is to insert a Veress needle, Hasson-type cannula, or dilating balloon directly into the preperitoneal space either at the hernia site or, preferably, just above the symphysis pubis. If the bladder has been drained by a catheter, as it should be prior to all extraperitoneal herniorrhaphies, the suprapubic site is fairly safe for gaining access.

Secondary ports are inserted under vision from a 10-mm laparoscope placed through the primary port as in transperitoneal procedures. The secondary ports should be placed lower down on the abdominal wall compared with placement during transperitoneal procedures to avoid violation of the peritoneum. Some authors have recommended placing all three ports in the midline: one at the umbilicus, one just above the symphysis pubis, and the third halfway between the other two. If inadvertent entry into the peritoneal cavity occurs, the gas can be allowed to escape continuously by inserting a Veress needle percutaneously into the peritoneal cavity. This will allow successful completion of the procedure in an extraperitoneal fashion if the peritoneotomy is small.

The anatomic structures are often difficult to identify from the preperitoneal perspective because the fatty and connective tissues are not uniformly compressed by a membrane (i.e. the peritoneum) and therefore obscure the distinctions that can be appreciated from the intraperitoneal perspective. Nonetheless, with continued insufflation and gentle manipulation of the peritoneum off the pelvic sidewall, the appropriate landmarks can be ascertained. The shiny white Cooper's ligament and bluish external iliac vein are often the best structures to identify first. Once oriented, the surgeon cleans off the transversalis fascia analogs and addresses the hernia sac as described earlier. Again, a deep indirect hernia sac should be amputated if it cannot be dissected easily off the spermatic cord. A significant cord lipoma should be resected to allow a better fit of the mesh around the spermatic cord.

The mesh is inserted and positioned as previously described. The same admonitions as for stapling the prosthesis during the transperitoneal procedure apply here. Always proceed with caution on the iliopubic tract and Cooper's ligament. Again, the necessity of mesh fixation is controversial.

The pneumoproperitoneum is released after removal of the ports under direct vision at a pressure of 5 mmHg, and sites are closed as described earlier.

Postoperative care

If only a laparoscopic herniorrhaphy has been performed, patients are discharged home from the recovery room unless unusual circumstances suggest the need for inpatient observation (e.g. abdominal discomfort, need for parenteral analgesics, or medically unfit for rapid discharge). An oral analgesic is prescribed routinely, although they often are used for only a few days, if at all. The patient is encouraged to resume normal activity the next day, except for heavy lifting, which is restricted for the first week. There may be some abdominal bloating after transperitoneal procedures, and an over-the-counter laxative may be helpful.

Results

A few large series on laparoscopic herniorrhaphy have been published (Table 95.3) [78–81].Operative times [78–80], morbidity, reoperation rates, and recurrence rates [81] have been shown to decrease as surgeon experience increases. The mean operative time may be as low as 30 min in experienced hands, but over twice as long for those still learning the procedure. Overall minor and major complication rates were 4.2% and 1.6%, respectively, for this series of studies. Nearly 95% of the patients underwent laparoscopic herniorrhaphy on an outpatient basis. The overall recurrence rate was less than 1%, though only two of the studies reported their follow-up time. Prolonged follow-up is necessary to determine the true rate of recurrence following laparoscopic repair.

Several randomized, prospective trials have attempted to compare the various techniques of laparoscopic inguinal herniorrhaphy with their open counterparts (Table 95.4) [82–86]. Operative times were consistently and significantly longer for laparoscopic herniorrhaphy as compared to open repair. Analgesic requirement may be lower for the laparoscopic repair as compared to open herniorrhaphy; however, there appears to be no

significant differences in hospital stay or recurrence rates. Three of five studies found decreased convalescence in the laparoscopy group, one study was equivocal, and one study found no significant difference. No significant difference in major or minor complications were demonstrated except for the study by Tanphiphat *et al.*, which found an increased rate of postoperative parasthesia in the open repair group as compared to the laparoscopic herniorrhaphy group (33% vs 12%, $P = .008$) [82]. In addition, Lal *et al.* found that all 25 patients in the laparoscopic group reported being "very satisfied" with the cosmetic results of their surgery while only seven patients (28%) in the open group reported being "very satisfied" ($P < .001$) [86].

Most of the randomized controlled trials comparing open repair to laparoscopic herniorrhaphy involve relatively small numbers of patients, thereby lacking the power to provide statistically reliable results. To enhance the value of individual studies, a meta-analysis of the individual trials was performed by the EU Hernia Trialists Collaboration, which involved 70 investigators in 20 countries [87]. Forty-one trials were identified involving 7161 patients. Individual patient data were available for 25 trials (4165 participants). Operative times were longer for laparoscopic repairs by an overall weighted mean difference of 14.81 min (95% CI 13.98–15.64, $P < .0001$). Of 3130 laparoscopic repairs, 85 (2.7%) were converted to open, while five (0.1%) among 3541 open procedures were converted to a laparoscopic repair.

Postoperative complications were uncommon. There appeared to be fewer hematomas (8.7% vs 10.5%, $P < .01$) and more seromas (5.8% vs 3.8%, $P = 0.001$) in the laparoscopy groups. Wound or superficial infections also appeared less frequently in the laparoscopy groups (Peto's odds ratio 0.45, $P < .0001$). There were only three cases of deep infection: one case of mesh infection in each group as well as a deep infection in an open, nonmesh group. Potentially serious visceral injury or vascular injury was more common in the laparoscopy groups compared to the open groups (15 vs 5). Six of seven visceral injuries occurred in the laparoscopic groups, consisting of four bladder injuries, one small bowel injury, and one punctured stomach. A single small bowel injury occurred in the open groups. Two postoperative bowel obstructions occurred in the laparoscopic arms. Only six port-site hernias were reported.

In all trials with data, time to return to normal activity was shorter in the laparoscopy groups with a difference of about 7 days ($P < .0001$). There were also fewer cases of persisting pain 1 year following hernia repair in the laparoscopy groups (13.8% vs 19.1%, $P < .0001$) as well as fewer cases of persisting numbness (7.2% vs 13.4%, $P < .0001$).

TAPP, transabdominal peritoneal repair; TEP, totally extraperitoneal repair.

In the laparoscopy groups, 86 (2.7%) recurrences were reported among 3138 repairs compared to 109 (3.1%) recurrences among 3504 open procedures ($P = .16$). The nature of the open repair influenced the comparative performance of both TAPP and TEP laparoscopic herniorrhaphy. Hernia recurrence was less common after laparoscopic procedures than after open nonmesh repair, but no difference was noted in comparison with open mesh repairs.

Subsequent to the above studies, a large, multicenter trial at 14 Veterans Affairs medical centers randomly assigned 1983 patients to either open mesh or laparoscopic mesh repair [88]. Recurrent hernias were more common in the laparoscopy group than in the open group (10.1% vs 4.9%), as were complications (39.0% vs 33.4%), including life-threatening complications (1.1% vs 0.1%). The recurrence rate associated with laparoscopic repair when performed by surgeons who reported having performed more than 250 laparoscopic repairs was less than half that of surgeons who had performed 250 or fewer. For open repairs, there was no significant difference in the rate of recurrence between the most experienced surgeons and those with less experience. Patients treated laparoscopically reported less pain on the day of surgery and at 2 weeks. The time to resumption of daily activities was shorter for those patients undergoing laparoscopic repair (median time, 4 days for laparoscopic repair vs 5 days for open repair).

Complications

General laparoscopic complications are reviewed in Chapter 101 and will not be covered here. A number of complications relatively specific to laparoscopic abdominal wall herniorrhaphy are described below.

Hematoma, seroma, and hydrocele

Diagnosis

Postoperative swelling in the groin, scrotum, or abdominal wall may represent hematoma, seroma, hydrocele, or early hernia recurrence. Subcutaneous fluid collections may be noted within a few days postoperatively, but collections deep to the abdominal fascia may not become apparent for a week or more. Hematomas may be painful and tender or may become firmer with time. Erythema, tenderness, and fluctuation should prompt the consideration of infection.

Etiology

Undetected or inadequately addressed laceration of abdominal wall vessels (inferior epigastric, circumflex iliac), inguinal–pelvic vessels (deferential, gonadal, external spermatic, cremasteric, obturator, external iliac), or their branches may produce hematomas. Interrupted lymphatics combined with postsurgical inflammatory processes or a retained hernia sac predispose to seromas and hydroceles. Gentle tissue handling minimizes these complications.

Prevention

Larger vessels are avoided with careful dissection. Risk of undetected vessel trauma, which may lead to postoperative hematoma formation, is minimized by limiting dissection of the hernia defects and cord structures. Mobilization of deep or large hernia sacs offers no therapeutic advantage.

Treatment

Conservative management is usually sufficient as uninfected fluid collections will likely resolve. In the event of disabling symptoms or suspected infection, operative drainage may be required. If the fluid contains bacteria and is isolated from the mesh, antibiotic therapy and percutaneous drainage are indicated. If the fluid is infected and in contact with the mesh, open exploration and removal of the mesh is indicated.

Infection of the prosthesis

Diagnosis

Erythema, tenderness, swelling, warmth, and fluctuance are the usual external signs of localized infection. Pain, fever, malaise, gastrointestinal disturbances, and leukocytosis may be the presenting signs if a deep abscess forms. Aspiration with microscopic and bacteriologic examination is indicated if infection is suspected.

Etiology

A prosthesis may become infected during manipulation or subsequently from direct or hematogenous spread.

Prevention

Although there are no specific data regarding mesh herniorrhaphy, the Infectious Diseases Society of America lists procedures that include the implantation of permanent prosthetic materials under the category "moderate evidence to support a recommendation for use" of surgical antimicrobial prophylaxis [89]. Broad-spectrum intraoperative antibiotic coverage of both skin and enteric organisms, such as a second-generation cephalosporin, is recommended. The usefulness of

continuing antibiotic administration postoperatively is doubtful. There is disagreement as to the need for antimicrobial prophylaxis to prevent hematogenous seeding during later invasive procedures (dental procedures, endoscopy, etc.) in a patient with an implanted prosthetic mesh.

Treatment

Incision and drainage with removal of the prosthesis are required.

Bowel adhesion to the prosthesis and bowel obstruction

Diagnosis

Abdominal pain, abdominal distention, and gastrointestinal disturbances are the signs associated with bowel adherence to the mesh with subsequent bowel obstruction.

Etiology

Most experimental evidence in animal models suggests that bowel adhesion to the prosthesis is most likely to occur after intraperitoneal herniorrhaphy and least likely to occur following TEP [90, 91]. Although PTFE is generally thought to incite less tissue reaction than polypropylene, one group found no difference between the two materials when placed intraperitoneally in a pig model [92]. However, adhesions in experimental animals after transperitoneal prosthesis placement, when they do occur, appear flimsy and do not involve the bowel [90, 91, 93]. Clinical experience suggests that this complication is unusual in humans.

Prevention

Based on the experimental findings noted above, careful closure of the peritoneum over the hernia defect is advised, if possible.

Treatment

Repeat laparoscopy with visualization of the repair site is appropriate for the patient who does not respond to a course of conservative management with intravenous hydration, bowel rest, and nasogastric suction. This will allow diagnosis of the cause of the bowel obstruction. Laparoscopic adhesiolysis may be considered, but open laparotomy is advised if there is any question of the ability to safely identify and manage the problem laparoscopically.

Nerve entrapment

Diagnosis

Pain due to nerve entrapment may be constant or intermittent, dull or sharp, burning or tingling. Hip flexion often diminishes the pain. There may be pain over the actual site of injury, and a light tapping at this site may cause an "electric" sensation down the course of the nerve [94]. Pain may be noted immediately after surgery or may become apparent over the next few weeks.

Etiology

A number of nerves are at risk for entrapment injury during laparoscopic herniorrhaphy, including almost any branch of the lumbar plexus. Entrapment most commonly involves the lateral femoral cutaneous nerve (causing meralgia paresthetica) or femoral branch of the genitofemoral nerve [94, 95]. These injuries occur when staples are placed medial to the iliopubic tract in the area lateral to the testicular vessels. Staples placed too deeply (through the transversalis fascia analogs into the internal oblique musculature) around the internal inguinal ring can entrap the ilioinguinal nerve, iliohypogastric nerve, and genital branch of the genitofemoral nerve [94].

Prevention

Careful staple placement, not using excessive pressure when firing staples into the abdominal wall, and avoiding the area medial to the iliopubic tract and lateral to the testicular vessels will prevent nerve entrapment. As discussed above, some surgeons have abandoned mesh fixation altogether.

Treatment

With analgesics and avoidance of activities that exacerbate the symptoms, most problems will resolve within 6 weeks. Local injections of anesthetics and corticosteroids may be helpful. If the symptoms persist beyond this period, laparoscopic removal of the offending staples may provide relief. If the duration since herniorrhaphy is prolonged (>3 months), neurolysis or neurectomy may be required since perineural fibrosis complicates the condition and may preclude resolution by staple removal alone [94].

Testicular pain or atrophy

Diagnosis

The complaint of a painful scrotum should prompt an evaluation with a careful physical examination and

urinalysis. Suspected epididymitis should be treated appropriately. Testicular torsion is unlikely in this setting but must be considered, especially if the onset of pain is acute.

Etiology

Neurovascular injury during manipulation of the spermatic cord or indirect hernia is presumably the cause of postoperative testicular complications.

Prevention

Avoiding unnecessary manipulation of the cord structures and indirect hernia sac will reduce the incidence of testicular injury.

Treatment

If infection and testicular torsion appear unlikely, then scrotal support and oral anti-inflammatory medication can be offered to provide symptomatic relief since the testicular pain will likely spontaneously resolve over the course of 1–2 weeks. Testicular atrophy is a potential complication of any hernia procedure and the patient should be counseled accordingly during the preoperative visit.

Internal herniation

Diagnosis

The patient will present with signs and symptoms of bowel obstruction.

Etiology

Failure to adequately close the peritoneum over the prosthesis during transperitoneal herniorrhaphy may allow bowel to slip through the peritoneotomy and produce obstruction [96, 97]. Herniation of bowel through the larger trocar sites is more common.

Prevention

Careful closure of the peritoneal defect and ensuring that each staple has a generous bite of tissue should prevent internal herniation. Similarly, fascial closure of larger port sites must be secure.

Treatment

Laparoscopy or laparotomy, as described earlier, will allow surgical correction of the problem. The repair can be left intact underneath the repaired peritoneal defect. Likewise, for a port-site hernia, the bowel contents are laparoscopically reduced and the hernia site closed by intracorporeal or extracorporeal suturing techniques.

Inguinal hernia recurrence

Diagnosis

A groin mass should be considered to be an inguinal hernia recurrence if there are no signs of infection and the mass is pulsatile with a Valsalva maneuver.

Etiology

Most recurrences of inguinal hernias following laparoscopic repair early in a surgeon's experience have been attributed to the use of prosthetic mesh of inadequate size.

Prevention

A sufficiently large piece of mesh should be used to cover all potential sites of herniation with generous overlap. A 7 × 12-cm piece of mesh is recommended as the minimum size for laparoscopic herniorrhaphy.

Treatment

Several authors have reported successful repeat laparoscopic herniorrhaphy following a recurrence. The urologist performing laparoscopic herniorrhaphy should refer a patient with a suspected recurrence to a general surgeon.

CHAPTER 96
Laparoscopic and Robotic Pyeloplasty in Children

Craig A. Peters
Division of Surgical Innovation, Technology and Translation, Sheikh Zayed Institute for Pediatric Surgical Innovation, Children's National Medical Center, Washington, DC, USA

Introduction

Pyeloplasty may represent the ideal pediatric urologic operation to be performed with laparoscopic techniques as the morbidity of the access is greater than that of the procedure. Reducing the access-related morbidity should provide a clinical improvement and to date, this appears to be the case. Laparoscopic pyeloplasty for pediatric applications, however, continues to evolve and is not yet the new gold standard. Indeed, it will be difficult to replace the current gold standard, open pyeloplasty, from an efficacy standpoint, with 97% success in most applications. Laparoscopy has shown equivalency, but in limited studies and with limited follow-up. There is certainly strong reason to believe that it can be equally effective and with less morbidity than open surgery, with continued advances in laparoscopic and robotic surgical technology. Nonetheless, it still remains to be clearly confirmed that laparoscopy can substitute for open surgery. For now, utilization of conventional and robotic laparoscopic technique are continuing to grow for pediatric pyeloplasty and this chapter will review the strategies, techniques, and outcomes of these methods, as well as discussing reoperative pyeloplasty for those in whom surgical success has not been achieved.

Background

Laparoscopic pyeloplasty was first described concurrently by Kavoussi and Peters [1] and by Schuessler *et al*. in 1993 [2]. Pediatric pyeloplasty in a 7-year old was reported by Peters *et al*. in 1995 [3]. There was slow application of the technique with isolated case series [4]. Several variations were tried to limit the need for intracorporeal suturing, which was the major technical challenge. Application of conventional laparoscopic pyeloplasty has been limited. Robotic technology has broadened the application of minimally invasive pyeloplasty and more rapid diffusion has followed. Subsequently, several series have reported very good outcomes, equivalent to open surgery, with robotic pyeloplasty. It should be noted that comparisons with laparoscopic pyeloplasty by those performing conventional laparoscopic pyeloplasty showed no major advantage to the robotic technology [5]. For those with advanced laparoscopic skills and without access to the current robotic systems, conventional laparoscopic pyeloplasty remains an established technique for treating ureteropelvic junction obstruction (UPJO) in children.

Indications

The indications for laparoscopic pyeloplasty, by any method, are identical to those for open pyeloplasty. These should not be anticipated to change significantly, as this procedure, even when performed with minimally invasive techniques, is still a significant operation. These indications in the asymptomatic child, particularly the infant, remain controversial. A significant decline in relative uptake on diuretic renography is usually taken

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

as a clear indication for surgery, as is increasing hydronephrosis. Whether a kidney that is contributing significantly less than its nonhydronephrotic mate at initial evaluation should undergo pyeloplasty remains highly controversial. Our practice is to recommend surgical intervention for severe hydronephrosis when initial uptake is less than 40%, there is a decline in relative uptake or an increase in hydronephrosis on follow-up, or if there is no improvement in the severity of hydronephrosis by 12–18 months of age.

In the symptomatic older child with hydronephrosis and lateralizing pain, with or without confirmation on diuretic renography wash-out times, surgical intervention for UPJO is appropriate. It is rarely needed to preplace a ureteral stent, and this may induce significant edema. Baseline assessment of relative renal uptake or function is useful to permit assessment of postoperative response.

The indications for reoperative pyeloplasty are much more subjective and may include pain, and persisting or worsening hydronephrosis or diuretic renal scan parameters. There is some value in an attempt at ureteral balloon dilation and stenting for 4–6 weeks, although there are few data to clearly indicate a definitive approach. This is likely due to the obvious fact that these patients are very individual.

The options of open, laparoscopic, and robotic approaches should be discussed with the family. If the family requests open surgery that choice should be honored, but this as yet has not occurred in our experience. The decision to pursue laparoscopic versus robotic pyeloplasty is based on availability of equipment and surgeon preference, as well as skill set.

Patient preparation

For all laparoscopic approaches, we have used a liquid diet for 24 h prior to surgery, and a single rectal suppository or oral bowel stimulant to clear the colon. This will facilitate operative exposure and postoperative comfort. Patients are given a preoperative dose of antibiotics and the family is consulted as to the choice regarding a preplaced or antegrade intraoperative stent. The preplaced stent is positioned with a retrograde pyelogram that offers a radiographic image of the ureter. While this is uncommonly useful, it may provide information to adjust the surgical approach. If there has been no imaging of the ureter, this is sometimes of value. The stent is then positioned optimally just below the UPJ under fluoroscopic guidance. This leaves the pelvis dilated to facilitate operative exposure (Figure 96.1). The distal coil of the stent is positioned in the bladder. An extraction string is left in place and secured to the perineum.

Stent sizing is based on age, using the formula of age plus 2 in centimeters for length. We use a 3.8F stent for children aged 3 months to 3 years, 4.7F for those aged 3–12 years, and a 6F stent for adolescents.

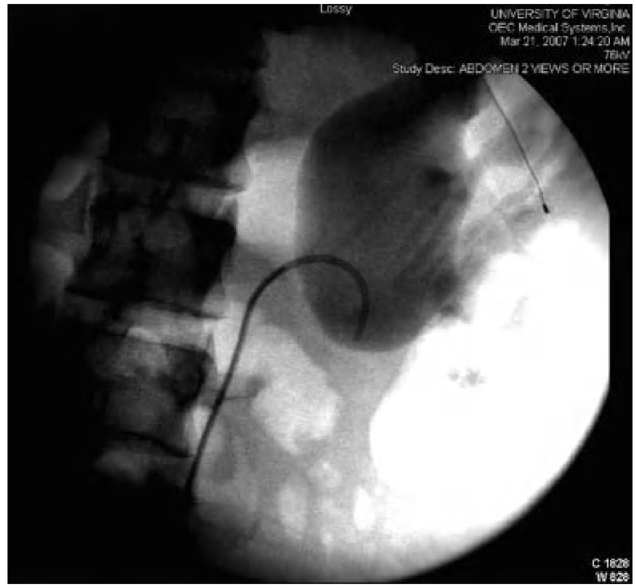

Figure 96.1 Double-J ureteral stent positioning prior to pyeloplasty. The curl of the stent is placed just below the ureteropelvic junction to allow it to be moved into the pelvis at the time of surgery, while maintaining renal pelvic distention, which facilitates exposure. An extraction string is left on the distal end of the stent to permit easy removal postoperatively (2 weeks postoperatively).

The patient is then positioned with a Foley catheter in place in a supine fashion for preparation.

Operative set-up

For both conventional laparoscopic and robotic pyeloplasty, the patient is positioned in the supine position for transperitoneal surgery. The ipsilateral side is elevated with a wedge or gel roll, the arm is braced alongside the body, and both arms are secured by a folded towel passed behind the patient and taped over the arms to the table (Figure 96.2). A chest strap and upper leg strap are taped in position as well to secure the child. The strapping is tested by rolling the patient prior to draping. Head position may need to be secured. Working closely with the anesthesia team is important in this. An orogastric tube is always placed. The patient is prepped over the entire abdomen from pubis to xyphoid.

Procedure

The basic procedure of a dismembered pyeloplasty (Anderson–Hynes) is identical for both robotic (illustrated) and conventional laparoscopic approaches. Alternative methods, although not practiced by us, are used and should be familiar to the reader.

Figure 96.2 Patient positioning for a left-sided pyeloplasty. The patient is secured to the table at the chest and thighs, with the ipsilateral flank raised 30° on a wedge. By rotating the table, the patient may be oriented flat to the floor for port placement, then with a steep tilt in the opposite direction to facilitate exposure of the pelvis and kidney.

Figure 96.3 Port placement for a left-sided pyeloplasty. In small children or those with a very severe hydronephrosis in which the ureteropelvic junction is lower, the inferior port should be moved more medially and inferiorly.

Conventional laparoscopic pyeloplasty

Transperitoneal laparoscopic pyeloplasty is performed using three ports. The endoscope is placed through the umbilicus, and two working ports are placed in a symmetric array, with one in the midline between the umbilicus and the xyphoid, and the second in the midclavicular line halfway between the umbilicus and the pubis. In smaller children where the UPJ is lower, the inferior working port should be placed inferior and medial to avoid being too close to the anastomotic area. This is particularly true of the robotic system (Figure 96.3).

Port placement is performed using an open technique where the inferior edge of the umbilicus is incised in a curvilinear fashion and the tissues dissected with cautery until the peritoneum is entered. This is usually readily apparent. At this point a box stitch is placed in the fascia to ensure a tight seal and permit rapid closure at completion [6]. The camera port is then placed. In robotic cases, this is the 12-mm binocular endoscope and for conventional cases a 3.5- or 5-mm endoscope. The abdomen is insufflated. We typically use 10–12 mmHg pressure.

Working ports are placed under direct vision with preplaced fascial box stitches in the fascia. For this we typically use 3-0 Vicryl on a CT-2 needle that is bent sharply to recreate a UR-6 needle curve. For older patients, a 2-0 suture with a UR-6 needle is used if available. This approach to port placement is used in all access for laparoscopic or robotic cases.

The degree of patient tilting is determined by direct inspection with the ports in place. The dilated renal pelvis is often visible on the left side through the mesentery and the optimal position is such that the small bowel falls away yet the left colon does not fall over the pelvis. This is usually about 45° and on the right, slightly steeper angulation is usually needed to expose the pelvis. On the right, the hepatic flexure is mobilized to reveal the pelvis and the duodenum may need to be mobilized slightly. On the left, a transmesenteric exposure is preferable but not always possible. If the pelvis is not visible through the peritoneum and the upper ureter readily identified, then a retrocolic approach is best performed. The splenic flexure is released and the colon is mobilized medially from the flexure to the iliac vessels. This offers an excellent view of the kidney and pelvis.

Once the pelvis is exposed (Figure 96.4), the proximal ureter is mobilized to permit pyeloplasty, but also to limit any devascularization. The periureteral adventitia is maintained and this usually provides adequate mobilization. On the left side, when a transmesenteric approach is used, the pelvis is mobilized similarly, but very little other tissue is moved. A hitch stitch is placed at this time to permit lifting and stabilization of the UPJ and proximal ureter. This is placed by passing a 3-0 needle with a monofilament suture through the abdominal wall and then through the pelvis. It is then passed back through the abdominal wall, lifted to the appropriate tension, and fixed. This provides stabilization of the anastomotic site, exposure, and lifting of the anastomotic area away from the pool of urine and blood. The degree of tension may be altered during the procedure as needed.

The pyelotomy is performed in order to have a dependent lower vertex of the pelvis that will be sewn to the inferior aspect of the ureteral spatulation (Figure 96.5). This should be the most dependent portion of the pelvis. The amount of pelvis removed should not be excessive, but in older children with a large pelvis, some reduction is reasonable. The portion of the lower pelvis and the actual UPJ now attached to the ureter are used as a handle for manipulation to avoid any touching of the anastomotic area (Figure 96.6). The ureter is spatulated on the lateral aspect until the normal ureter is encountered, which usually opens widely (Figure 96.7).

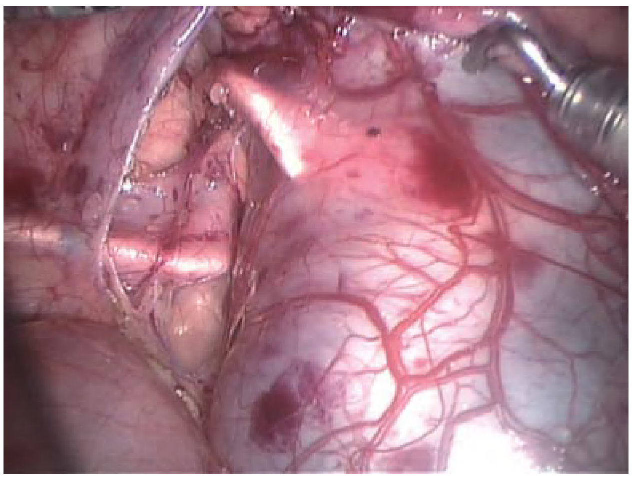

Figure 96.4 Laparoscopic view of the double-J sent at the ureteropelvic junction, just below the dilated pelvis.

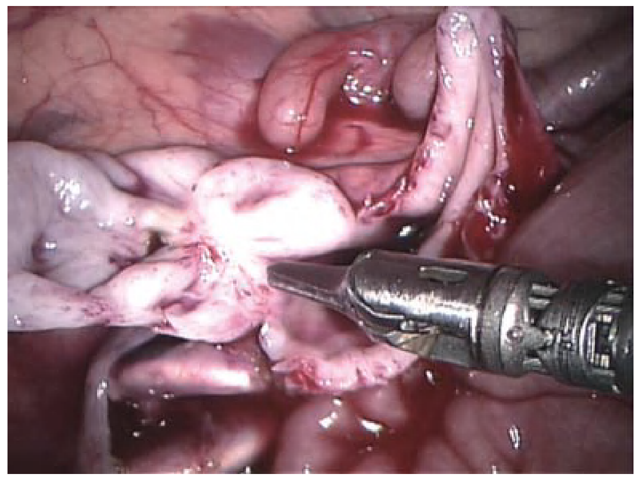

Figure 96.6 Completion of the pyelotomy, exposing the stenotic ureteropelvic junction at the tip of the scissors. The excised pelvis is used as a handle to permit control of the ureter without touching the anastomotic site.

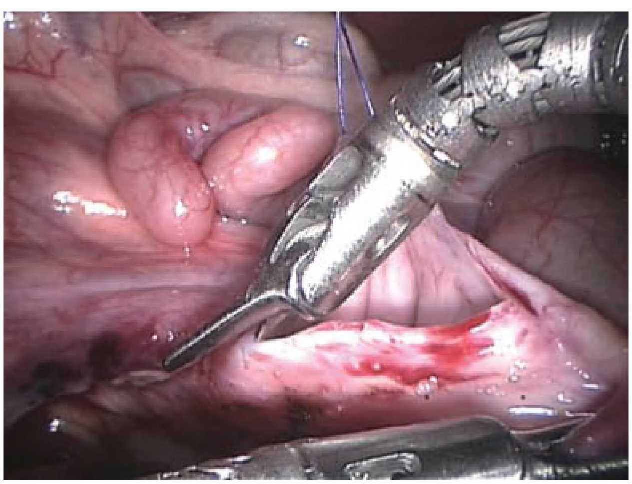

Figure 96.5 Initial pyelotomy on the anterior wall of the right-sided ureteropelvic junction. The hitch stitch is visible just behind the robotic scissors (5 mm).

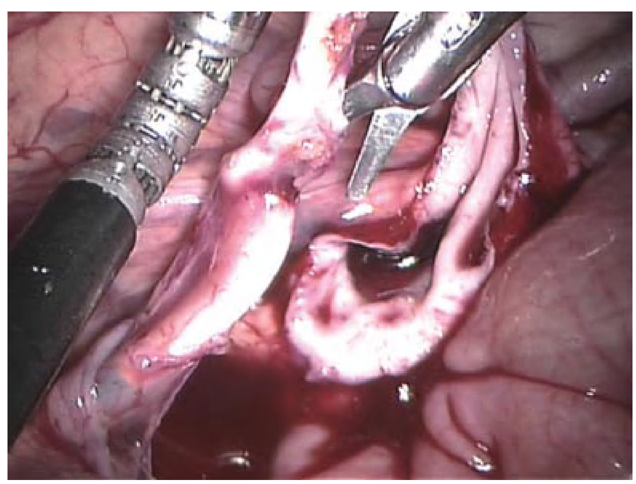

Figure 96.7 Spatulation of the lateral aspect of the proximal ureter through the stenotic segment until the ureter opens freely.

The anastomosis is begun at the inferior aspect of the spatulation and the inferior most aspect of the renal pelvis (Figure 96.8). Care is taken in placing this stitch. The posterior wall (usually) of the anastomosis is then performed with a running suture (Figure 96.9). We usually use an absorbable monofilament suture, with 5-0 used in children aged from 5 to 12 years and 6-0 for younger children. If a stent had been placed beforehand, it can be used to move the ureter around during the anastomosis, avoiding direct contact. After the back wall is completed, the stent may be placed into the pelvis, or if one has not been preplaced, an antegrade stent is placed. The handle of the pelvis and UPJ is excised (Figure 96.10).

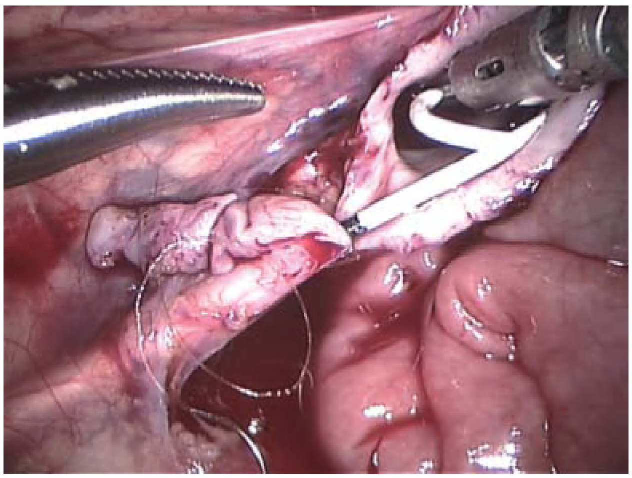

Figure 96.8 Start of the anastomosis with the initial vertex stitch placed at the inferior-most aspect of the spatulation. The anterior wall will be closed first. The choice of which wall to close first depends on the orientation of the pelvis. The stent has been moved into position in the dilated renal pelvis.

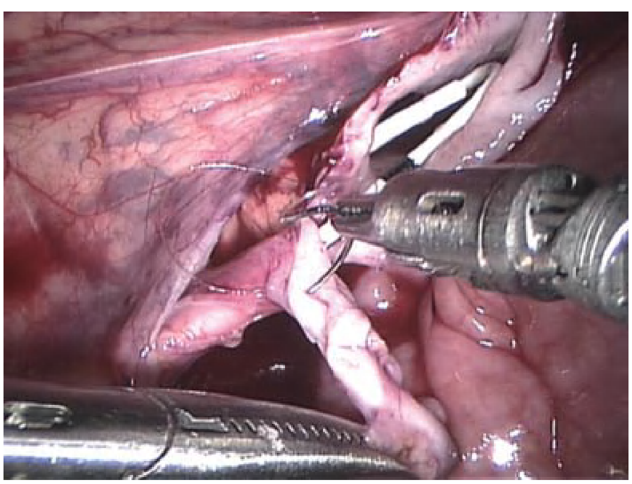

Figure 96.9 Continuation of the anterior wall closure with a running, simple suture line of 6-0 monofilament absorbable material.

Stent placement is performed by passing a 14G angiocatheter through the abdominal wall, and passing a guidewire and preloaded stent through the angiocatheter. This size will accommodate up to a 4.7F stent. If a larger stent is needed for older patients, it can be passed directly through the abdominal wall. The guidewire is passed down the ureter and the stent follows, with guidance from inside the abdominal space. Positioning is by feel and movement of the stent, as well as using rough guidelines for stent size (age + 2 in centimeters). Some authors recommend filling the bladder by clamping the bladder catheter and watching for reflux of urine through the stent, or by instilling blue dye in the bladder. Ultrasound confirmation of stent position is also suggested. We have not found these measures to be necessary.

Following stent placement, the opposite wall of the anastomosis is completed (Figures 96.11–96.13). Some

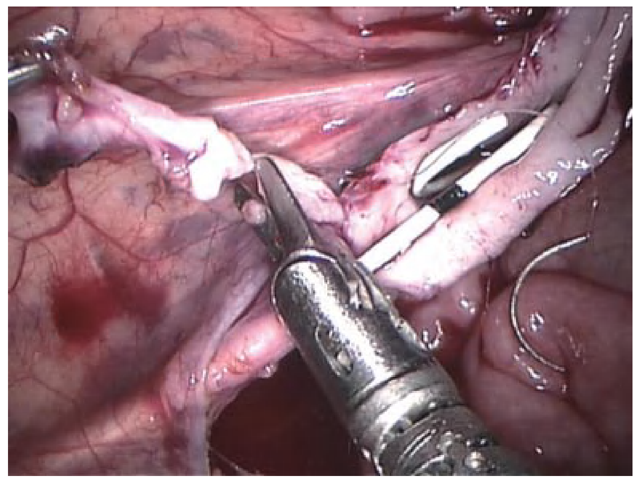

Figure 96.10 After the anterior wall is nearly completely closed, the extrarenal pelvis is excised.

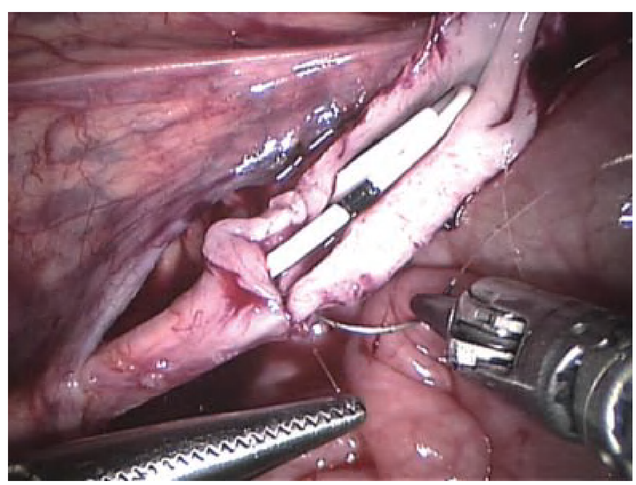

Figure 96.11 Start of the back wall closure.

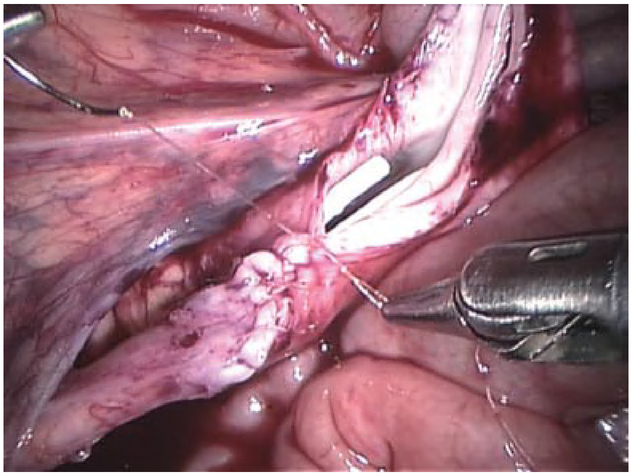

Figure 96.12 Completion of the ureteral-to-pelvic anastomosis.

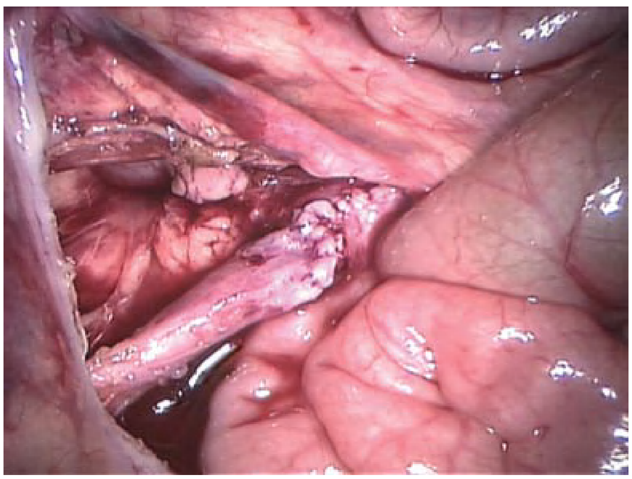

Figure 96.13 Closure of the pyelotomy is now complete.

have suggested testing the integrity of the anastomosis, but it should be recognized that an acutely water-tight anastomosis is unrealistic and testing seems unnecessary [7]. With adequate drainage, this approach heals well. No wound drain is used as long as the stent is in place, and the Foley catheter is left in place overnight.

If the stent cannot be placed, the options are to leave a perinephric drain, positioned posteriorly, or to place a nephrostomy. We have not found the latter to work well, as it can be both difficult to place and does not drain well. If the anastomosis was technically successful, a simple wound drain would seem reasonable. There have been reports of routinely not using a stent, and it is clear that this can be successful, yet seems to be an unnecessary risk when modern stents are well tolerated and seem to be generally free of problems, as compared to the potential issues when they are not used, including the need to urgently drain a urinoma or place a percutaneous nephrostomy. With stents placed retrograde in over two-thirds of pyeloplasties, permitting simple string extraction, there is little ground to argue for taking the extra risk of performing these repairs without a stent.

Robotic pyeloplasty

Robotic pyeloplasty is performed nearly identically to conventional laparoscopic pyeloplasty, using a transperitoneal approach [8]. Retroperitoneal pyeloplasties have been performed and a large series has been reported with good outcomes [9]. The youngest child reported was 1.7 years. The overall conversion and complication rate was higher than in most reports. One of the issues of note for retroperitoneal pyeloplasty has been the potential to miss the presence of an anterior crossing vessel and subsequent persisting obstruction.

We have used a three-port technique consistently and with a hitch stitch can avoid the need for a fourth port for exposure of right-sided operations.

The lower age limit for robotic pyeloplasty has not been defined, and in practice only newborns are not undergoing robotic repair. Given the success and feasibility of neonatal robotic procedures in general surgery [10], use of the robotic system in neonatal pyeloplasty seems reasonable.

There are no differences between management intraoperatively or postoperatively for robotic pyeloplasty and conventional laparoscopic pyeloplasty. The principle considerations are those of port placement and several aspects are critically important.

Both 5- and 8-mm working ports are currently available and, while it is preferable to use smaller ports, they are not as well suited to working inside the abdomen of a small child, given that they require a greater distance to turn. The distance inside the body is nearly twice as long as a comparable 8-mm instrument, due to the articulating mechanisms. For infants, we use 5-mm instruments, but set the port position further away from the surgical area. In small infants, this can mean moving the upper port from the midline to the contralateral side, and more importantly, the lower port moves medially and inferiorly, at times being in the midline. We have used three ports in the midline as the set-up for bilateral infant pyeloplasties and simply redocked the robot on the opposite side of the patient.

In performing the operation, care is taken with all instrument exchanges since there is some movement away from the last position and the space tolerances are small. Sutures are brought through the ports, and the 5-mm cannulas can accommodate 5-0 sutures on fine needles. The needle is brought in using a conventional laparoscopic instrument grasping the suture, not the needle. Alternatively, the needles may be passed directly through the abdominal wall in small children. Irrigation

is performed using one of the working arms and a conventional laparoscopic suction device with the patient-side assistant controlling movement.

Vascular hitch procedures (Hellstrom)

An alternative approach to correcting UPJO associated with a lower pole crossing vessel is the vascular hitch or Hellstrom procedure [11]. In cases where the UPJO is associated with a crossing vessel that appears to be the cause of the obstruction, mobilizing the renal pelvis inferiorly and wrapping the vessel in the pelvis above the anatomic UPJ can successfully relieve the obstruction. Although introduced many years ago, and rarely performed with open surgery, this technique has taken on a new life with laparoscopic approaches.

At present the Hellstrom technique is being used in cases where there is a clear crossing vessel in which there is visible peristalsis after moving the UPJ away from the vessel. The ureter must appear fairly normal. The vessel is then wrapped in a sling of pelvic tissue that keeps the UPJ below the vessel. This assumes that there is no intrinsic obstructive element at the UPJ, and several reports have attempted to justify this with apparently normal pathology of the UPJ [12]. The method itself is simple and straightforward and avoids a dismembered repair.

The concerns regarding this approach are several. It is unclear if the crossing vessel has induced a change in the functionality of the UPJ and if this can be accurately recognized at surgery. We have seen several cases where the ureter appeared wide open and peristalsing, even without a crossing vessel and clear obstructive effect. Patients have also been seen who had intermittent obstruction based on symptoms and imaging, yet had no crossing vessel. This indicates that the anatomic arrangement of the UPJ can be abnormal without a crossing vessel. Therefore, the vessel may have little to do with the functional abnormality and the real pathology is not visible to the operator. The reports are of limited number and rarely indicate the denominator of pyeloplasties [11, 13]. This seems a risky approach to a straightforward problem for which there is an effective and efficient solution in a dismembered pyeloplasty.

Fenger plasty

Another alternative to the standard Anderson–Hynes pyeloplasty is the Fenger plasty [14], which is essentially a Heinecke–Mickulicz plasty of the UPJ. It is performed by incising the lateral aspect of the UPJ longitudinally and closing it transversely, opening up the narrowed UPJ. This is feasible with only a few sutures and has been described with a purpose-built endoscopic instrument [15]; yet results do not achieve the success levels of a dismembered repair [16] and there is little experience in children.

Postoperative follow-up

Postoperatively, the stent is removed at 2–4 weeks after surgery, and a renal ultrasound is performed 4–6 weeks after stent removal. If the degree of dilation is equal to or less than it was preoperatively, the kidney is rechecked in 3 months. If there is hydronephrosis greater than preoperatively and it is not massive, a follow-up ultrasound is performed in 6 weeks. This will nearly always show further improvement, often marked. If there is persisting or worsening dilation, a functional study is performed, such as a MAG-3 or even an intravenous pyelogram, to confirm some function in the involved kidney.

Complications

The most significant complication of pyeloplasty is persistent obstruction. This may be due acutely to edema or blood clot, and chronically to stenosis or kinking. Determining whether a persistently dilated kidney is still obstructed remains difficult. Persisting symptoms are a clear indication of the need for intervention, but most are without pain. If the degree of hydronephrosis in a child does not improve to a clear degree within 4–6 months, then it should be assumed that there is still obstruction. At this point the options include performing a diuretic renogram to assess function and drainage. Alternatively, a stent can be placed with or without balloon dilation of the UPJ, which is our choice. The stent is usually left in place for 4–6 weeks to provide some passive dilation. After stent removal, the kidney is reassessed with ultrasound. Persisting evidence of obstruction, either with or without symptoms, would prompt a reoperative pyeloplasty. Further dilation and stenting is probably of little value.

The other common complication associated with a pyeloplasty is persisting urinary drainage if a drain was left in place. This is not as common today as few drains are used with indwelling stents. On occasions, with a stent, the child will not void and develops urinary ascites due to backflow through the stent across the anastomosis. In such situations, a Foley catheter is replaced and left in place for 5 days to permit healing, and the child left to resume normal voiding.

Laparoscopic complications associated with a pyeloplasty are those that might affect any laparoscopic procedure, including bowel injury, adjacent organ injury, and port-site infection. The incidence is low, probably due to the excellent visibility during laparoscopic procedures in children. Nonetheless, there is a higher risk of severe injury due to the size and physical

characteristics of children if care is not taken with all aspects of the procedure, including access and operative manipulation [17].

Reoperative pyeloplasty

When drainage through the UPJ is not adequate following surgical repair, reoperative pyeloplasty may be needed. Reoperative pyeloplasty has been performed in children using an identical port set-up and operative strategy as for a primary pyeloplasty [18], although in a small fraction, an alternative repair may be needed, such as a Y–V plasty when there is excessive scarring, or a ureterocalycostomy in a markedly fibrotic pelvis [19]. This is never a decision taken lightly and it must be considered very carefully. Ongoing symptoms, loss of relative function or clear increases in dilation are indications for reoperation. More difficult reasons include persistent but stable hydronephrosis and evidence of impaired drainage on diuretic renography. As noted above, a single attempt at ureteral dilation and stenting may be tried. This is successful in some patients, perhaps up to 50%, although there are no data to support this. If there is persisting evidence of obstruction, reoperation is likely the best course. Endopyelotomy has been reported as a useful measure for reoperative cases, yet our experience has been very unsatisfactory with endopyelotomy in cases of prior pyeloplasty. At present, reoperative laparoscopic pyeloplasty is the treatment of choice for persisting obstruction after pyeloplasty.

Preparation and set-up are identical to the initial pyeloplasty. Exposure of the UPJ is often difficult due to scarring, but often not as difficult in cases of prior open repair, as these are usually done retroperitoneally. Even with intraperitoneal laparoscopic approaches, the degree of scarring is often limited. In some, however, the scarring is intense and this must be anticipated. We have used a Y–V advancement approach in some cases when dismemberment is not possible. Otherwise, the UPJ is mobilized and the stenotic portion removed. A spatulated reanastomosis is performed with an indwelling stent, usually as wide as possible. This is left in place for at least 4 weeks and up to 6 weeks. No drain is left in place. These patients tend to do well, although they may remain in hospital a little longer than those undergoing routine primary repairs. Follow-up is similar.

Clinical outcomes

Multiple reports of pediatric laparoscopic pyeloplasty and a few of robotic procedures in children have demonstrated safety and efficacy, with results equivalent to open surgery. Operative times are longer, but are decreasing with experience. Success rates between 95% and 100% can be anticipated (Figure 96.14) with minimal risk of complications. There have been very few significant intraoperative complications recorded, and most are due to urine leakage and persisting obstruction [20]. There have been no randomized prospective trials to date, and this may now be difficult to accomplish [21]. There have been four studies with direct comparisons between techniques, yet all have addressed different techniques and had limited numbers [5, 8, 22, 23]. Two meta-analyses have shown equivalent results between open and conventional laparoscopic and robotic procedures [24, 25]. It should be recognized that all these assessments have been made relatively early in the development and dissemination of these procedures, and results should be viewed in this light [26].

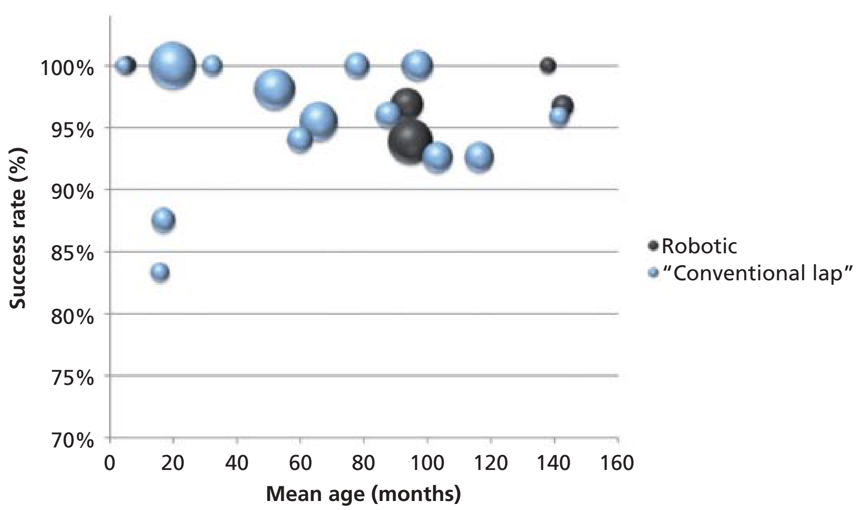

Figure 96.14 Success rates in pediatric laparoscopic and robotic pyeloplasty and mean age of patient in the reports. Patient age has no clear effect on success rate. The size of the bubbles indicates patient numbers.

Conclusions

Laparoscopic pyeloplasty has become an established aspect of the armamentarium of the pediatric urologist in some centers, while in others it remains experimental. With robotic technology the ability to accurately and effectively perform this procedure has become more accessible, and it has become more widely used. The specific advantages may be difficult to confirm in small children, but the older child and certainly the adolescent recovers more rapidly than with open surgery. Most may be discharged on the first postoperative day. While some surgeons will therefore limit its use to those over a certain age, we use robotic technology in all pediatric patients undergoing pyeloplasty except for the rare newborn, and even this is not a strict distinction. If there is a discernable benefit for the older child, there is likely a benefit for an infant, even if we are not able to discern the benefit using current methods. The operative visibility and the rapid recovery characteristic of laparoscopic and robotic pyeloplasty argue strongly for minimally invasive pyeloplasty in all children. Continued efforts to enhance the operative methods, the intraoperative manipulation, and the means to assess perioperative morbidity will help in determining the ultimate role of these new technologies in pediatric care.

CHAPTER 97

Pediatric Laparoscopic and Robot-Assisted Laparoscopic Renal Surgery

Brian A. VanderBrink[1] & Michael C. Ost[2]

[1]Division of Urology, Nationwide Children's Hospital, Columbus, OH, USA

[2]Division of Pediatric Urology, Children's Hospital of Pittsburgh, Department of Urology, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Introduction

Laparoscopy in urology may be considered to have its beginning in the field of pediatric urology. Cortesi *et al.* pioneered the use of laparoscopy as a diagnostic tool for localizing nonpalpable undescended testicles in 1976 [1]. A considerable amount has changed over the last three decades. Minimally invasive surgery in the form of laparoscopy has evolved from a diagnostic to a therapeutic and reconstructive technique. Laparoscopic renal surgery has almost become the standard in adults, while in the pediatric setting it continues to gain momentum. This chapter discusses minimally invasive renal surgery utilizing laparoscopic techniques, with and without robotic assistance, in pediatric practice.

History

Since Clayman *et al*. first described the laparoscopic radical nephrectomy (LRN) in an adult, it was inevitable the technique would be applied to children [2]. It is thought that the first LRN to be performed in a child occurred in Boston; however, the first published report of LRN in a child was performed at the University of California-Los Angeles in 1992 [3]. Shortly thereafter, additional reports describing the safety and feasibility of LRN in children appeared in the literature [4, 5]. The first published report of laparoscopic radical nephroureterectomy (LRNU) in a child was by Das *et al*. for a nonfunctioning refluxing renal unit [6]. The initial published report in 1993 of a laparoscopic partial nephrectomy (LPN) performed in a child for a ureteral duplication anomaly came from Eastern Virginia Medical School by Jordan and Winslow [7]. This same institution applied laparoscopic techniques for performing one of the earliest reported laparoscopic pyelolithotomies [8]. Renal cyst decortications, calyceal diverticulectomy, and nephropexy are additional upper tract procedures that have also been performed with a minimally invasive approach utilizing laparoscopy.

Robot-assisted renal laparoscopic surgery in children has been an area of increasing interest. The merits of the robot-assisted approach are fully realized for reconstructive procedures such as pyeloplasty or ureteral reimplantation, given the degree of motion of the instrumentation. LRN is rarely a technically complex procedure in the pediatric population and large series in the literature reporting robot-assisted LRN are lacking. One of the first pediatric robot-assisted renal laparoscopic procedures to be published was a case report of bilateral heminephroureterectomies by Pedraza *et al.* in 2004 [9]. Many of the same renal procedures described earlier without robot assistance have now been performed with robotic assistance.

Technical considerations/differences between children and adults

The technical considerations when comparing adult and pediatric laparoscopic cases translate into port sizes and an appreciation for the greater compliance of a pediatric abdomen compared to an adult patient. With

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

regard to port size, whether it is an adult or pediatric abdomen, a limiting factor will be the instrument used to address the renal hilum: If a stapling device is to be used, a 12-mm port must be placed. Depending on vessel size, 5- or 10-mm titanium or Hem-o-lok clips will require a 5- or 10-mm port, respectively. In the pediatric patient, there are instances where renal vasculature is small enough (<7 mm) that a coagulating device (i.e. 5-mm LigaSure or Harmonic scalpel) is sufficient to address the renal hilum, e.g. a nephrectomy on a non-functioning multicystic dysplastic kidney with atretic vessels.

Whether a nephrectomy is performed in an infant, toddler, teenager, or adult, a basic "triangulation" trocar format is utilized, with subtle modification, depending on age (Figure 97.1). More compliant abdomens of the infant, toddler, and preschool child will require a more "curved" configuration in order to maximize exposure and ergonomics during a nephrectomy (Figure 97.2).

The highly compliant pediatric abdomen (compliance = volume/pressure) limits the use of a direct visual obturator to gain access to the abdomen prior to nephrectomy as the risk for injury to other intra-abdominal structures dramatically increases (Figure 97.3). In this regard, an open Hasson or Baliez technique is always used at the umbilicus to place the initial camera port.

It is not uncommon for children to require bilateral laparoscopic procedures. In such instances, only one additional trocar and repositioning may be required (Figure 97.4).

Specimen extraction is a function of the size of the kidney and whether or not morcelation will be employed. The umbilical trocar, used for a 5- or 10-mm telescope, may be lengthened cephelad to remove a specimen. Alternatively, a separate Pfannenstiel incision can be made to extract the kidney. This suprapubic incision may have some cosmetic value in the pediatric population.

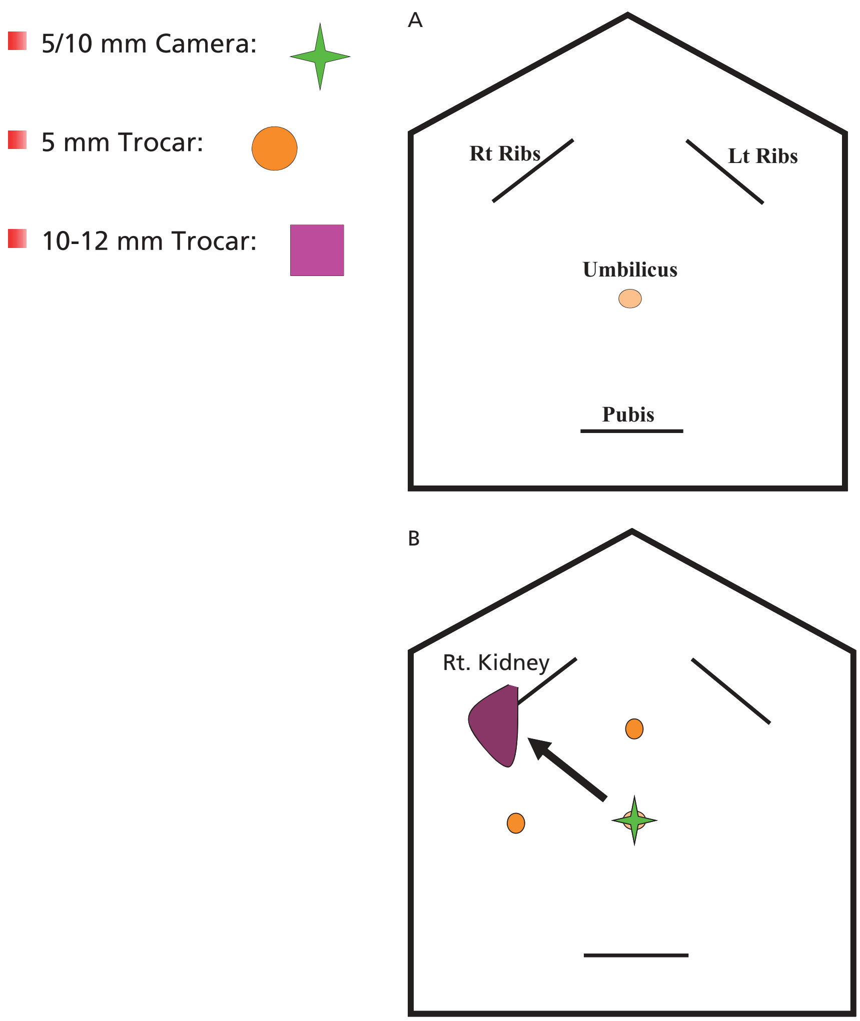

Figure 97.1 Trocar placement in renal surgery. (A) Abdominal grid and guide in adult or pediatric patients undergoing laparoscopic renal surgery. (B) Principle of "triangulation" guides port placement for laparoscopic renal surgery. Triangulation aligns the working trocars directed at the renal hilum, maximizing surgical ergonomics.

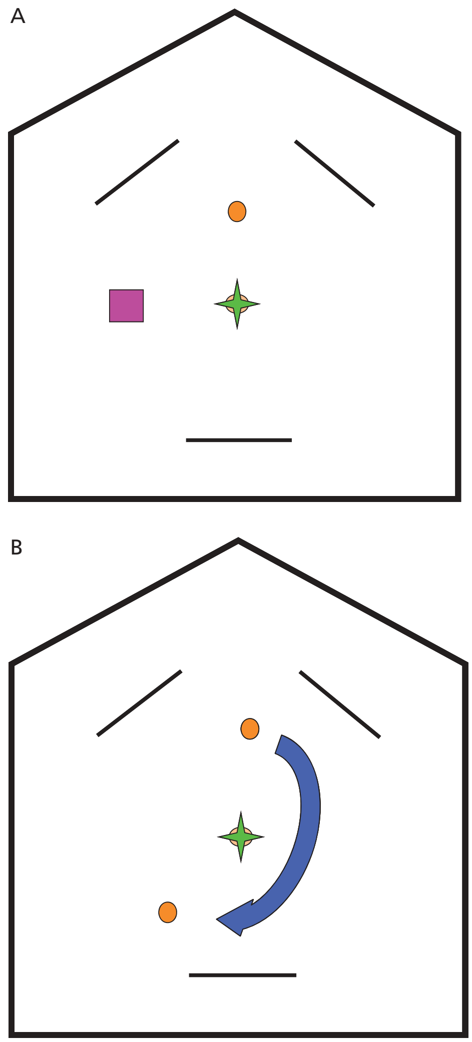

Figure 97.2 Trocar placement in laparoscopic renal surgery: nephrectomy, upper pole nephrectomy, partial nephrectomy, and pyeloplasty. (A) In the adult, the main working port is usually placed in the ipsilateral lower quadrant at the level of the umbilicus. In the case of a nephrectomy, the renal hilum is most often stapled via the 12-mm port with an endovascular stapler (60 mm). (B) In children, the "triangular" configuration is opened to give a more "curved" alignment. The right lower quadrant main working port is dropped cephalad in order to maximize working room and ergonomics. The examples are shown for right renal surgery; for left renal surgery, trocar placement would be a mirror image of this. See Figure 96.1 for key to trocar ports.

Access to the peritoneum/retroperitoneum for laparoscopic renal procedures

Laparoscopic renal surgery can be performed by either a retroperitoneal or transperitoneal approach, and this will determine patient positioning and trocar placement.

Transperitoneal approach

One of us (BV) routinely performs renal laparoscopic procedures via a transperitoneal approach because of the increased working space compared to with the retroperitoneal approach. Robot-assisted laparoscopic renal surgery needs to be accomplished via a transperitoneal approach in young patients, given the size limitations necessary to avoid robotic arms hitting one another during the procedure.

The patient is placed in a modified flank position with the surgery side rotated up by approximately 30°. A gel roll placed behind the back assists in providing this rotation. All pressure points are well padded and the patient secured to the table with wide adhesive tape across the shoulders and hips. A "test roll" is performed prior to draping by rotating the table to ensure stable patient positioning. This involves rotating the table away from the surgery side of the patient. This maneuver allows the intra-abdominal viscera to fall away from the operative field to assist in exposure. The abdomen from the xyphoid process to the mons pubis and ipsilateral flank is sterilely prepped and draped. A urethral catheter can be placed on the sterile field intraoperatively or prior to draping, depending upon surgeon preference and the procedure to be performed. Nasogastric suction can decompress the stomach prior to trocar insertion.

Pneumoperitoneum can be established via a Veress needle placed through the rectus fascia at the umbilicus or open Hasson technique. With the placement of the Veress needle the surgeon should appreciate two separate layers that represent the needle traversing the rectus sheath and peritoneum. Correct Veress needle placement in the peritoneum is confirmed by aspiration with no withdrawal of blood or fecal matter and maintenance of a low pressure (<10 mmHg) upon insufflation of CO_2. The Hasson technique involves incision through the skin and, under direct vision, the rectus sheath is opened just enough to accommodate the size of the trocar being placed. Entry into the peritoneum is performed sharply and the trocar placed into the cavity. Insufflation can begin to obtain pneumoperitoneum. Open access techniques are most often used in children to minimize the risk of abdominal organ injury.

Passeroti *et al.* have recently shown in a single institution study of over 800 pediatric urologic laparoscopic procedures that no statistically significant difference exists between the two techniques with respect to access-related complications [10]. They reported an incidence of 2.3% with a Veress needle compared to 0.8% when an open Hasson technique was utilized. The authors determined that while the overall complication rate was low in their series, surgeons who performed more than 12 laparoscopic surgeries annually had a lower

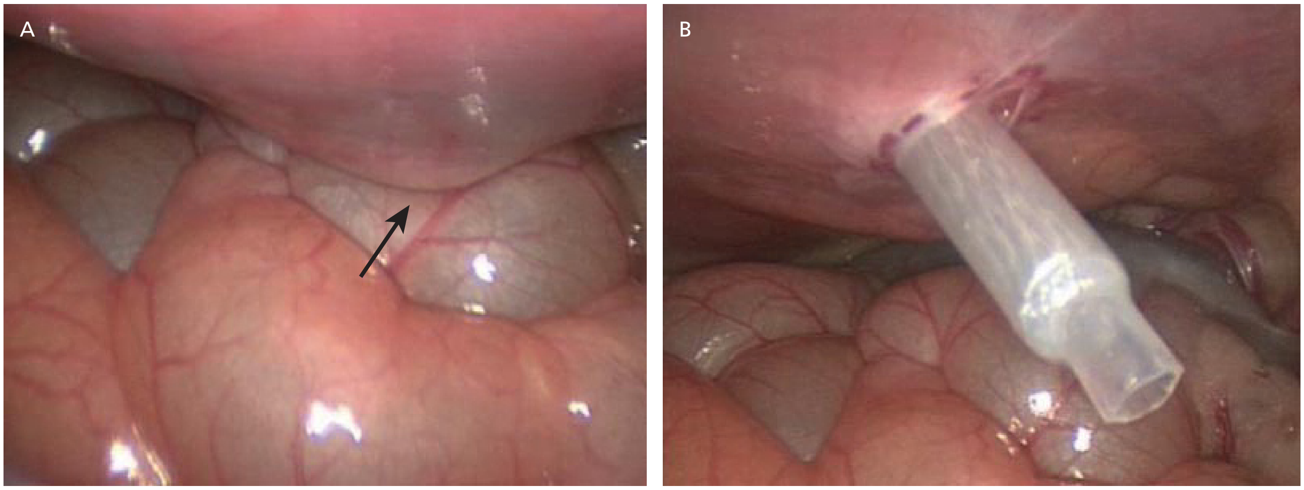

Figure 97.3 The highly compliant pediatric abdomen offers little resistance when insufflated. Use of a direct visual obturator may increase the risk for organ injury. (A) Even under direct vision, trocar placement places the anterior abdominal wall in close proximity to the bowel (arrow). (B) 5-mm dilating step trocars are most often used.

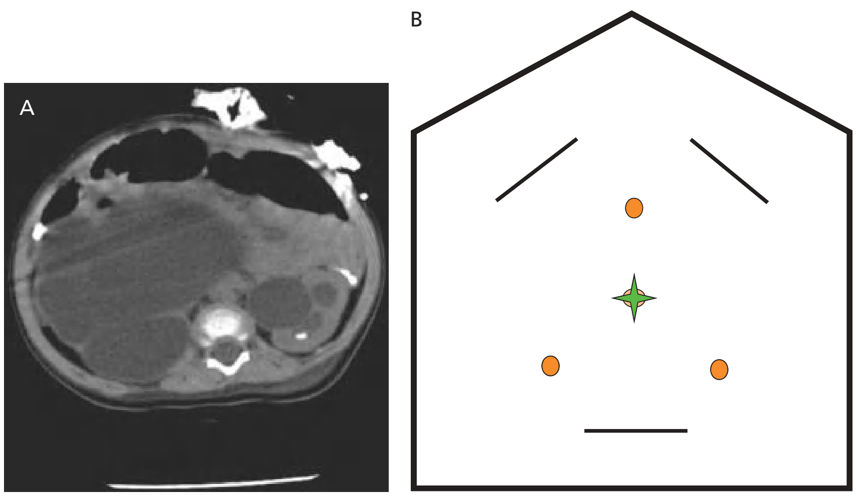

Figure 97.4 This 4-yearold boy with bilateral ureteropelvic junction obstructions (UPJOs) underwent simultaneous laparoscopic renal surgeries. A left laparoscopic pyeloplasty was first performed. Repositioning and additional placement of a right lower quadrant port (5 mm) allowed for a laparoscopic nephrectomy to be performed on a dysplastic nonfunctional renal unit resulting from a UPJO. See Figure 96.1 for key to trocar ports.

complication rate compared to less active laparoscopic surgeons.

Optical visualization during initial trocar placement can be performed when using a Veress needle. This is accomplished with a 0° lens placed through the obturator of the trocar (i.e. XCEL trocar; Ethicon Endo-Surgery Inc, Cincinnati, OH, USA) that provides a continuous ability to see through all layers of the abdominal wall while obtaining access to the peritoneal cavity. Following making a skin incision large enough for the trocar to pass easily; the lens, obturator, and trocar are inserted through the abdomen. Once entry into the peritoneal cavity is confirmed, the trocar is advanced a few more millimeters and the obturator and camera are removed. Reinsertion of the camera alone through the trocar can then allow for unimpeded inspection of the peritoneum and the path taken by the previously placed Veress needle.

Retroperitoneal approach

Advocates of the retroperitoneal laparoscopic nephrectomy cite that open renal surgery is performed extraperitoneally and that a minimally invasive technique should replicate the established technique. Additionally, with the kidney being a retroperitoneal organ, a retroperitoneal approach is the shortest distance to the kidney. Theoretically, injury to peritoneal structures should also be less with a retroperitoneal approach. The major disadvantage of a retroperitoneal laparoscopy is

the limited working space relative to the transperitoneal method. Histories of prior retroperitoneal surgery or infectious process are considered relative contraindications for the retroperitoneal approach as the dense adhesions encountered in these situations hinder dilation of the retroperitoneal space.

Patient positioning can either be prone or flank when utilizing a retroperitoneal approach. The prone approach takes advantage of gravity as the kidney falls anteriorly, facilitating hilum exposure. There is also less chance for peritoneal violation with a prone approach. The flank approach provides a greater working space and slightly more access to the distal ureter. Trocar placement will differ depending upon patient position. When the patient is in the flank position, initial access can be accomplished via the open Hassan technique. An incision is typically made off the tip of the 12th rib; dissection of the flank musculature down to the lumbodorsal fascia is performed. This fascia is then opened only enough to allow for placement of a finger and the retroperitoneal space is entered. A larger incision runs the risk of air leak during insufflation of the retroperitoneal working space. Blunt dissection with the finger to create a space that can accommodate a dilating device is the next step. For the prone approach, initial access is gained with the patient in the full prone position using a subcostal incision at the edge of the paraspinous muscles and the 12th rib, and this is developed with blunt dissection through the latissimus and oblique muscles.

Expansion of the retroperitoneal space is necessary to allow for visualization of the surgical field and the addition of working ports. This is usually accomplished with a balloon inflation device, either one that is commercially available or one crafted out of a surgical glove placed over a red rubber catheter and affixed with suture. Commercially available devices will only be useful for the older patient and therefore the surgical glove technique is more commonly employed. The dilating device is placed into the retroperitoneum and filled with saline to expand the potential space. The volume of saline instilled to achieve adequate space is typically around 150–200 mL, depending upon the size of the patient. Following removal of the dilating device, a trocar can be placed into the retroperitoneum. A tight seal is created with a suture passed through the fascia and cinched up the tissue around the trocar. Alternatively, a blunt-tipped trocar (US Surgical, Norwalk, CT, USA) is used to seal the trocar site and, because of its low profile, it should not obstruct the view or working space. The retroperitoneum is then insufflated with CO_2 to allow for additional ports to be placed.

There are limited reports of the safety and feasibility of robot-assisted laparoscopic renal surgeries. The size of the robotic arms and need for adequate spacing between them makes a retroperitoneal more difficult than a transperitoneal robotic procedure.

Radical nephrectomy/nephroureterectomy

Indications

There are several indications for removal of a kidney with a partial or complete ipsilateral ureter. A nonfunctioning or poorly functioning kidney may result in recurrent episodes of urinary tract infections (UTIs). LRNU can be a highly successful procedure to eliminate subsequent UTIs in nearly all cases of a poorly functioning kidney secondary to vesicoureteral reflux. In the case of a single system kidney drained by an ectopic ureter and poor function, an extirpative approach may be preferred over reconstructive efforts. In this instance, the decision to perform a LRN alone or LRNU is left to the surgeon. The ureteral stump does carry a risk of infectious complications if retained, albeit very small. Similarly, a nonfunctioning renal unit secondary to obstruction, most commonly from ureteropelvic junction (UPJ) obstruction, can also serve as a risk factor for UTI or urolithiasis. Once again, depending upon whether the obstruction is located proximal or distal, a LRN or LRNU, respectively, may eliminate this risk.

Renal masses, both solid and cystic, have the potential to harbor malignant elements, with that risk being higher with solid masses. Certain age groups may help to predict the pathology of the mass, but surgical exploration is warranted when radiographic characteristics are ambiguous. Multicystic dysplastic kidney (MCDK) is a frequent cystic abnormality encountered by the pediatric urologist. Local symptoms such as respiratory compromise or gastric outlet obstruction have been reported due to the mass effect of MCDK, with nephrectomy alleviating these problems [11]. Many MCDKs spontaneously involute with time; however, a small percentage will enlarge over time. Extremely rare case reports of malignant elements within a MCDK can produce anxiety in both physicians and parents, which may prompt surgical intervention, although it is estimated that approximately 2000 nephrectomies would need to be performed to treat one case of Wilms tumor [12]. Originally considered a contraindication to LRN; reports of LRN for Wilms tumor have been described. Many of these LRNs are performed after neoadjuvant chemotherapy to decrease tumor size prior to surgery.

Operative technique

Transperitoneal approach

Additional working 5-mm trocars can be placed as needed. One trocar is placed in the midline beneath the

xiphoid process. To complete a triangulation pattern around the renal hilum, an additional 5-mm trocar is placed lateral to the umbilicus at the anterior axillary line on the ipsilateral side where surgery is to be performed. When performing a LRNU, this lateral trocar is displaced inferiorly to make it easier to reach the distal ureter. However, in most small children, it is rare not to be able to reach the pelvis with a standard triangular port configuration. An additional modification of standard trocar placement may be necessary in the obese patient. Placement of the working trocars in a more lateral position may be advantageous as the working distance from the midline to the kidney is greater as body mass index increases.

When performing a robot-assisted LRN or LRNU, even greater attention must be given to the placement of the working trocars. This is due to the possibility of the robotic arms crashing into each other during their movement. A general rule of thumb is to place the robotic working trocars at a minimum of 8 cm from the camera to minimize the potential for this problem. Another difference between the robot-assisted approach and pure laparoscopy is that the camera necessary for robot-assisted renal surgery will need to be larger than 5-mm to take advantage of the three-dimensional (3D) imaging capabilities of robotic system. This is because smaller lenses are monocular and cannot provide a 3D image. A fourth trocar will be necessary for the bedside assistant to use laparoscopic suction or to apply clips. After placement of all trocars, the robotic device is docked from the ipsilateral side and the robotic arms are engaged. The robot has several instruments (scissors, needle drivers, and graspers) that are available in both 8- and 5-mm sizes.

Mobilization of the colon and adjacent structures that are anterior to the kidney is the first step. Incision of the white line of Toldt with mobilization of the colon medially will expose the retroperitoneum and Gerota's fascia. Identification of the ureter provides the surgeon with a familiar landmark. Anterior traction on the ureter will define the posterior limit of the dissection in the retroperitoneum. This maneuver performed near the hilum also places the renal artery and vein on stretch during their dissection prior to ligation. Safe visualization of the operative field for a left-sided LRN is usually not difficult following adequate mobilization of spleen and descending colon. However, for a right-sided LRN, the liver may obscure the operative field. A grasping laparoscopic instrument can provide anterior retraction of the liver and maintain the retraction after grasping the lateral abdominal wall. This results in markedly improved visibility, but care must be taken not to grasp the diaphragm, which may result in tear and pneumothorax. Alternatively, a 5-mm "snake retractor" may be passed through a subcostal trocar to retract the liver (Figure 97.5).

If LRN is being performed due to concern over a potential renal malignancy, the dissection should remain outside of Gerota's fascia. Following adequate mobilization of adjacent organs and with anterior traction of the lower pole of the kidney and ureter, hilar structures should be easily identified. Lateral dissection of the kidney is inadvisable at this point because the kidney will rotate after losing this point of fixation, resulting in obscuring the hilar structures upon anterior traction of the lower pole of the kidney. The renal arteries associated with MCDK are typically small in caliber, with the renal vein being of normal size. Individual isolation of the renal artery and vein is advised prior to separate ligation of the vessels with clips. A laparoscopic stapler can be used to control the renal vessels, but these devices require upsizing any existing 5-mm trocar as they will fit only through a 12-mm trocar. Following division of the renal vessels, the dissection continues along the superior medial aspect of the kidney. Adrenal-sparing LRN is performed by clear visualization of the adrenal tissue, which is sharply distinct from the now devascularized kidney. It is at this point that dissection along the lateral border of the kidney should proceed and medial traction of the kidney easily displays the proper surgical plane to follow. Aggressive dissection along the posterior aspect of the upper pole should be avoided as the diaphragm is close and there is the risk of tear. Caudal displacement of the kidney allows for identification of any remaining attachments of the kidney. These attachments should be cauterized as they often contain blood vessels because they are located near the inferior border of the adrenal gland. Once avulvsed these vessels may retract and can be difficult to find and control.

If a LRN is the only procedure to be performed, then the kidney can be separated from the ureter at this point with the specimen placed into a laparoscopic specimen retrieval bag. However, if a LRNU is to be performed, then maintaining continuity of the ureter with the kidney may be preferred, allowing for easier cephelad traction of the ureter to assist in distal dissection. Care must be exercised as the ureter crosses anterior to the iliac vasculature. In the male, knowledge of the location of the vas deferens during pelvic ureteral dissection is essential to avoid injury. For the refluxing ureter, following its division from the bladder, closure of the ureter is necessary to avoid postoperative leakage from the stump. This can be accomplished with intracorporeal suturing with absorbable suture or with an EndoLoop ligature. In contrast, most surgeons will leave a nonrefluxing obstructed ureter open after transection.

The kidney and ureter can be placed into a laparoscopic entrapment sac and removed *en bloc* or

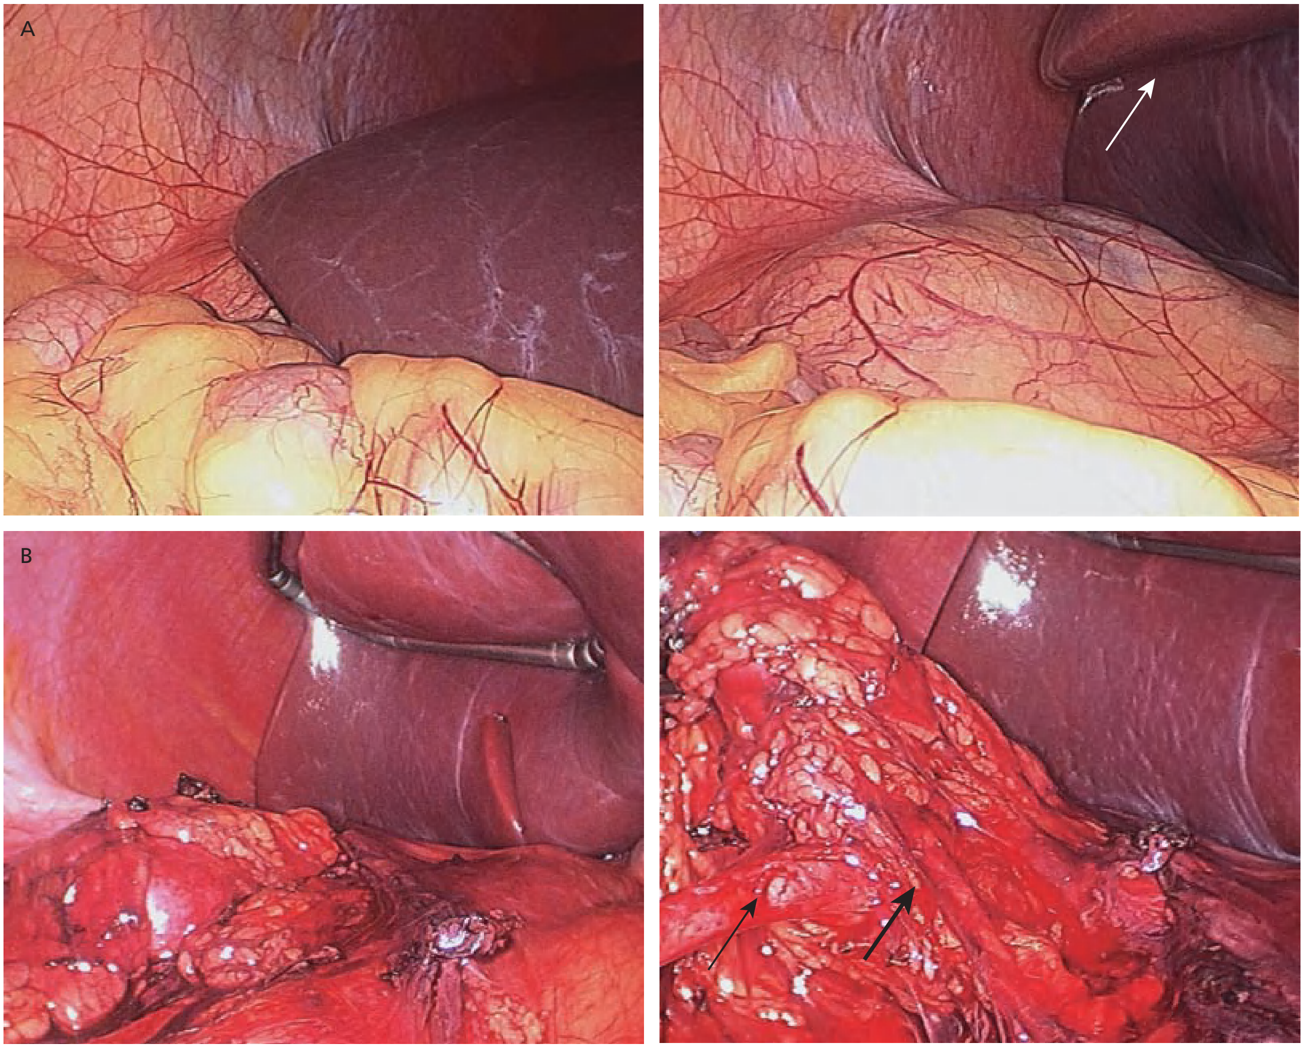

Figure 97.5 Liver retraction during right renal surgery. (A) During right laparoscopic renal surgery, the liver may often obscure and hinder dissection of the kidney (left). An additional midline trocar may be placed and an instrument can be placed to the side wall retracting the liver and sustaining it on a bridge (arrow) (right). (B) A "snake" liver retractor can also be used through a right subcostal trocar to expose the right kidney (left). View of the right ureter (thin arrow) and hilum (thick arrow) prior to nephrectomy (left).

morcellated depending upon the indication for surgery. Following removal of the surgical specimen, the operative field is inspected and hemostasis insured. Decreasing the insufflation pressure may reveal venous bleeding that is under tamponade at higher pressures. We recommend closure of all trocar sites greater than 3 mm in diameter in children. The Carter–Thomason device is especially helpful in fascial closure of the trocar sites. The skin is closed with a subcuticular suture.

Retroperitoneal approach

For the retroperitoneal flank approach, a working trocar is placed posterior to the initial incision after inserting a finger into the retroperitoneum while directing the trocar onto the tip of the inserted finger. The posterior trocar combined with a camera in the retroperitoneal space allows for the development of the space medial to the initial trocar for placement of the anterior trocars. This is accomplished using a dissector or aspirator to push the peritoneum medially, and additional trocars are placed under direct vision. This peritoneal sweeping maneuver must be performed carefully to avoid injury to the peritoneal reflection, which could result in a tear in the peritoneum, resulting in significantly reduced insufflation of the peritoneum and a smaller retroperitoneal working space. For the prone retroperitoneal approach, secondary working trocars are placed above the iliac crest just lateral to the paraspinous muscles and just medial to the peritoneal reflection.

Once all the necessary trocars have been placed, the initial step is identifying the border between the psoas muscle and lower pole of the kidney. Similar to a transperitoneal approach, subsequent identification and upward traction on the ipsilateral ureter assists in identifying hilar structures. Lateral traction on the kidney places the hilum on stretch for dissection and visualization. The renal artery is more clearly visualized with retroperitoneal laparoscopy compared to the transperitoneal approach as it is located posterior to the renal vein. Each vessel can be clipped and transected with similar methods to those described for transperitoneal laparoscopic renal surgery. Anterior dissection results in the kidney falling onto the hilum, and to maintain adequate visualization of the hilum, anterior dissection of the kidney with the flank approach should be avoided prior to transection of the vessels. Remaining perinephric attachments can be released with blunt and electrocautery dissection as previously described . The ureter is transected and the specimen placed into a laparoscopic entrapment sac. The kidney and ureter can be removed *en bloc* or morcellated, depending upon the indication for surgery. Trocar site closure is performed as previously described.

Postoperative care

The nasogastric tube placed intraoperatively is removed prior to the patient leaving the operating room. Patients can be started on clear liquids on the day of surgery and advanced to a regular diet upon return of bowel function. The urethral catheter can be removed the morning after surgery in uncomplicated LRN. Ketolorac is a very useful analgesic in the immediate postoperative period as an adjunct to the judicious administration of narcotics. Ketolorac should not be used in patients with renal insufficiency. Most patients remain in hospital for 24–48 h after surgery.

Outcomes

The safety and efficacy of LRN and LRNU for benign disease in children have been firmly established since their first descriptions [13–45]. The rate of conversion from a laparoscopic planned approach to open renal surgery is very low in published series (Table 97.1), and there does not appear to be significant disparity in conversion rates between pediatric series of LRN and LRNU. Transperitoneal or retroperitoneal approaches to laparoscopic renal surgery, in the hands of an experienced surgeon, appear to have comparable operative times. The advantages of laparoscopy for renal surgery in infants may be less than in other age groups given the typical rapid convalescence of this age group. Multiple studies have been conducted comparing intraoperative and postoperative outcomes between open and laparoscopic renal surgery. These comparative studies typically demonstrate increased operative times with a laparoscopic approach but a shorter hospital length of stay relative to the open cohort.

LRN for Wilms tumor has been reported, nearly always following neoadjuvant chemotherapy to downsize the primary tumor [46–49]. The pseudocapsule that is induced by chemotherapy may decrease the risk of tumor rupture and allow for safer manipulation of the tumor during LRN. In the largest series to date in 15 children, is that by Duarte *et al*. reported no intraoperative complications and sufficient lymph nodes were obtained to allow proper staging [49]. Using this minimally invasive approach, no local recurrences have been reported. Barber *et al.* described a series of LRN as the initial therapeutic modality in cases of suspected Wilms' tumor [47]. However, LRN for the treatment of Wilms' tumor has not yet established itself as the standard of care and has been performed only by experienced laparoscopic surgeons given the complexity of these cases.

Miscellaneous procedures

The application of laparoscopy to reconstructive surgical procedures of the kidney was inevitable after safety and efficacy was demonstrated for extirpative renal surgery. Laparoscopic pyeloplasty is covered in Chapter 86 and ureteroureterostomy is covered elsewhere in this textbook; however, there are many other renal procedures in which patients have appreciated the benefits of a laparoscopic approach.

Laparoscopic pyelolithotomy

The majority of surgically-treated stone disease in children is managed with established endourologic techniques, such as extracorporeal shock-wave lithotripsy, ureteroscopy or percutaneous nephrolithotomy (PCNL). However, laparoscopic pyelolithotomy has been described in pediatric patients who have failed established first-line stone therapies or those with large stone burden [50–54]. Pyelolithotomy has typically been performed concomitantly with correction of UPJ obstruction. Renal ectopia can make obtaining access for PCNL challenging and laparoscopic pyelolithotomy has been reported as an alternative in these unique circumstances [50].

A transperitoneal or retroperitoneal approach has been employed with removal of the stones accomplished *en bloc* with laparoscopic instruments when possible. Alternatively, if the stone cannot to be removed *en bloc*, it can be fragmented. The stone pieces can then be retrieved with a cystoscope and stone basket inserted into one of the trocars, with subsequent manipulation into the kidney through the pelviotomy. The use of an

internal or external drain is recommended following suture closure of the pelviotomy. Immediate stone-free rates have been reported to be 75–100% in this very challenging patient population, although in a very limited number of patients.

Laparoscopic calyceal diverticulectomy

Calyceal diverticula are infrequently encountered and can be complicated by stone formation or infection. Once again, endourologic techniques, such as ureteroscopy and percutaneous ablation, are the most commonly utilized procedures when treatment is necessary. Anterior calyceal diverticula are less amenable to access with the percutaneous surgical approach and an alternative surgical approach may be more appropriate given the patient's anatomy. To date reports of pediatric patients with laparoscopically treated calyceal diverticulum with or without robotic assistance have been published [55–57]. Indications for surgery were enlargement, pain, calculus or infection. Transperitoneal or retroperitoneal laparoscopic marsupialization and ablation of the diverticulum with electrocautery have been the techniques described. No complications or recurrences have been reported.

Laparoscopic renal denervation with nephropexy

Autosomal dominant polycystic kidney disease (ADPKD) will typically present in the adult population, but it can present in the pediatric age group. Pain is a common symptom and is hypothesized to be secondary to cyst enlargement resulting in compression of surrounding tissues, traction on the renal pedicle, and distention of the renal capsule. Casale *et al.* described a series of 12 patients, with mean age of 12 years, who underwent laparoscopic renal denervation for increasingly medically refractory flank pain [58]. The authors' technique involved splanchnic denervation via extensive dissection of the renal hilum and subsequent division of all perihilar nervous tissue. Full mobilization of the kidney and nephropexy with six 2-0 absorbable sutures completed the procedure. With average follow-up of 2 years, all treated patients were no longer taking analgesics and postoperative visual analog pain scores were significantly lower than preoperative scores.

Laparoendoscopic single-site surgery

The success of minimally invasive surgery in the form of laparoscopic surgery has inspired surgeons to improve the procedure. Decreasing the incisions from a traditional three ports to a single site has been the next evolution of laparoscopic renal surgery in children. The umbilicus is a naturally occurring scar and serves as the most utilized location for laparoendoscopic single-site (LESS) surgery. Potential benefits of LESS nephrectomy over traditional laparoscopic and open nephrectomy include improved cosmesis, reduction in iatrogenic visceral and vascular injuries from port placement, and possibly reduced cost from fewer ports. The first published report of transumbilical single-site LRN in a child was by Park *et al*. in 2009 [59]. In a 3-year-old girl a single ectopic ureter associated with dysplastic kidney was removed through a single incision in the umbilicus with a homemade single-port device. Subsequent LESS renal surgeries in children have been published with successful outcomes [60–62]. Innovations in current laparoscopic instrumentation will be necessary to make LESS an easier procedure to perform given the close proximity of working instruments at the single-port access site.

Extirpative surgery without skin incisions appears to be the ultimate in minimally invasive procedures in the abdomen. Natural orifice transluminal endoscopic surgery (NOTES) has been performed in a limited number of adult patients, either transvaginally or transgastrically [63]. Procedures have included cholecystectomy, appendectomy, and tubal ligation. NOTES transvaginal nephrectomy has been reported in an adult for atrophic kidney associated with recurrent UTIs [64]. While no NOTES urologic procedures have been reported in children, based upon history, we can only wait to see when this technique will be reported in a child. However, the enthusiasm to pursue a new surgical technique must be surpassed by the surgeon's ability to decide whether the new technique offers additional benefits over existing techniques and at no greater risk.

CHAPTER 98

Minimally Invasive Techniques in Lower Urinary Tract Reconstruction

Arun Srinivasan,[1] Gianmarco Isgrò[2] & Salvatore Micali[2]

[1]Arthur Smith Institute of Urology, North Shore – Long Island Jewish Health System Health System, New York, NY, USA

[2]Department of Urology, University of Modena & Reggio Emilia, Italy

Introduction

Minimally invasive surgery has an ever expanding role in urologic surgery. Particularly with the advent of robotic assistance, minimally invasive techniques have taken a major role in innovating and improving patient care. Although urologists have been among the first adapters of laparoscopy and robotics, pediatric urology to some extent has lagged behind this growth and innovation. However, in recent years, there has been a newly inspired growth and interest in adapting minimally invasive techniques in pediatric urology. We will discuss some of the most prominent of these surgical techniques and reported early results with them.

Vesicoureteral reflux surgery

Vesicoureteral reflux (VUR) represents the retrograde flow of urine from the bladder to the upper urinary tract during bladder emptying or filling. VUR can be primary, which is secondary to a congenitally incompetent ureterovesical junction (UVJ), or secondary, which is associated with other functional or organic dysfunction of the urinary tract leading to damage of the UVJ.

The goals of VUR treatment are to prevent pyelonephritis, renal injury, and other complications of reflux. The rationale of medical treatment of VUR is based on the historical finding of Ransley and Risdon in 1978, that sterile urine reflux does not cause renal scarring, and daily antibiotic prophylaxis has been the cornerstone in the initial management of children with reflux. Prophylaxis usually is continued until reflux resolves or until the risk of reflux to the individual is considered to be low. There are several medical therapy schemes available for VUR treatment; however, medical management of VUR needs a very close radiologic and laboratory follow up [1–3].

Since the first report by Puri *et al.* [4], endoscopic ureteral orifice bulking agent injection has become a more mainline treatment of reflux in children. The American Urological Association (AUA)_ in its present recommendation for reflux recognizes endoscopic injection of bulking agents as a mainline treatment [5]. The gold standard in the same document, however, remains open surgery to correct reflux, either intravesically or extravesically. Recently, surgeons have tried to simulate this success with open surgery in a minimally invasive fashion.

Robotic/laparoscopic extravesical reimplantation

Technique

The extravesical approach can be performed unilaterally or bilaterally, applying the Lich-Gregoir technique. The patient is placed in the supine position for an extravesical laparoscopic ureteral reimplantation. A ureteral catheter is placed to help laparoscopic identification and a Foley catheter to drain the bladder. Pneumoperitoneum is created via a Verres needle placed under the umbilicus or under direct vision, a first 5-mm trocar for vision

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

is placed, and the other two trocars are placed along the lateral border of the rectus. The ureter is identified at the level of iliac vessels and the pelvic portion of the ureter is dissected free all the way to the detrusor by dividing the posterior peritoneum on the surface of the bladder. Adequate exposure of the posterior bladder wall is a key factor in this operation. A hitch stitch through the posterior bladder wall can be used to improve the exposure of the ureteral hiatus, attaching to the abdominal wall or through it. Once the ureter is free, the size of the tunnel is estimated after the bladder is partially distended. The ureter should course slightly laterally to avoid kinking of the ureter. A tunnel is adequately dissected to obtain a 5:1 ratio of length to width; the detrusor muscle is divided full thickness using a cautery hook while keeping the mucosa intact and the bladder is inflated at this point to make this dissection easier. Any perforations of the mucosa are closed using a 6-0 chromic suture. The ureter is positioned in the tunnel so as to avoid any kinking or excessive compression of the ureter to prevent obstruction. Closure may be from the proximal end of the incision to the distal end or in the reverse fashion. In the latter, the ureter is well visualized while in the former the needle needs to be passed under the ureter each time. The peritoneum is closed in a running fashion. Robotic extravesical reimplant mirrors the laparoscopic technique, but obviously provides better three-dimensional visualization and easier intracorporeal suturing.

A common problem is accidental bladder mucosal perforations during the dissection of the detrusor muscle trough for the sub-mucosal tunnel. The bladder mucosa perforations can be prevented by not over distending the bladder and use of blunt instruments like the suction tip to do the dissection of the mucosa from the detrusor muscle. Other limitations of this approach are transgressing the peritoneal cavity and difficulty in bladder retraction for want of better exposure.

Outcomes

Lakshmanan *et al*. reported extravesical laparoscopic reimplant in 99 ureters in 66 children aged 4–18 years [6]. With the first 13 cases (the initial learning curve) of their series excluded, they reported a success rate of 97.8% with a mean follow-up of 34 months. Shu *et al.* in 2004 took a similar approach and documented excellent results and recovery in postpubertal patients [7]. Lopez *et al*. reported their experience with 43 renal units with reflux in 30 children (17 unilateral and 13 bilateral) [8]. The mean operative time was 70 min for unilateral reflux and 124 min for bilateral reflux. At the same time as the procedure, one heminephrectomy and two ureteroceles were removed by laparoscopy and endoscopy, respectively. Urine leakage necessitated a redo reimplantation in one patient and one patient with bilateral VUR had voiding difficulty.

Casale *et al*. reported on 41 children undergoing bilateral robotic extravesical reimplantation for VUR [9]. Patients were 16–81 months old and the mean operating time was 2.33 h. On follow-up the overall success rate was 97.6%. It has been customary not to perform bilateral extravesical reimplantation of the ureters due to increased incidence of voiding dysfunction. However, it is important to note that none of these patients developed voiding dysfunction in spite of performing bilateral extravesical reimplant. The authors attribute this to the nerve-sparing approach that they used due to better visualization by the robot. Leissner *et al*., in their landmark article, described the relationship of the pelvic nerves to the ureter, and argued that the preservation of these nerves protects voiding function [10].

Transvescicoscopic reimplanatation

Technical aspects

The port placement is preceded by transurethral cystoscopy to allow placement of the first camera port under cystoscopic guidance. The bladder is first distended with saline and a 2-0 monofilament traction suture is passed percutaneously at the bladder dome under cystoscopic vision, through both the abdominal and bladder walls to keep the bladder wall from falling away. A 5-mm trocar is then inserted under cystoscopic vision. A urethral catheter is then inserted to drain the bladder and start CO_2 insufflation to 10–12 mmHg pressure. The urethral catheter is used to occlude the internal urethral meatus to secure CO_2 pneumovesicum and it can also serve as an additional suction irrigation device during subsequent dissection and ureteric reimplantation. A 5-mm 30° scope is used to provide intravesical vision. Two more 3–5-mm working ports are then inserted through the lateral wall of the distended bladder under vesicoscopic guidance

Ureteral catheters are inserted into the respective ureter as a stent to facilitate subsequent ureteral mobilization and dissection, and secured with suture. Intravesical mobilization of the ureter, dissection of the sub-mucosal tunnel, and a Cohen's type of ureteral reimplantation are then performed under endoscopic guidance, in a similar manner to the open procedure. Once adequate ureteral length is obtained, the muscular defect in the ureteral hiatus is repaired. A sub-mucosal tunnel is then created as in an open Cohen's procedure. A fine grasper is passed and the mobilized ureter is gently drawn through the tunnel. Ureteroneocystostomy is performed under endoscopic guidance with intracorporeal suturing. Persistent mild hematuria up to 72 h has also been observed, which settles spontaneously.

Outcomes

The first report on a minimally invasive approach for intravesical reimplant was published by Gill *et al.* in 2001 [11]. This initial report utilized a combination of vesicoscopic and endoscopic instruments with good results. Canon *et al.* compared open cross-trigonal ureteral reimplant with vesicoscopic reimplant [12]. Fifty-two children underwent vesicoscopic reimplant and 40 underwent open reimplantation of the ureter. Although the mean age (5.7 vs 4 years) was significantly higher in the vesicoscopic group and the mean reflux grade was significantly lower, outcomes were comparable in the two groups of patients, both with resolution rates more than 90%. The vesicoscopic group of patients had significantly less requirement for postoperative analgesia. Valla *et al*. reported a similar success rate for vesicoscopic cross-trigonal reimplantation of ureters for reflux [13]. Peters *et al*. adapted the robot to perform vesicoscopic cross-trigonal reimplantation of the ureters [14].

Ureteral reconstruction

Laparoscopic transureteoureterostomy

An indication for this procedure is inadequate length of the affected ureter due to proximal or mid-ureteral damage leading to the inability to perform either an ureteroneocystostomy with or without a psoas hitch or a Boari flap. The rationale for this procedure, first described in 1930 by Higgins, is to restore the continuity of the urinary tract and to spare a renal unit, without need for permanent external drainage (i.e. ureterocutaneostomy, pyelostomy) [15]. The only report of a pediatric series of laparoscopic transureteoureterostomy (TUU) was published in 2007 by Paggio and Gonzalez, in three patients [16].

Using three working ports, both the ureters are mobilized. The donor ureter is then divided and this ureter is passed underneath the sigmoid mesentery to be anastamosed to the recipient ureter on the other side. Laparoscopic TUU features magnification, allowing delicate movements during the procedure and helping in the performance of a precise anastomosis; one drawback of this procedure is the need for advanced laparoscopic skills and a lengthy operative time.

Robotic/laparoscopic megaureter tapering and reimplant

Minimally invasive techniques to reconstruct the megaureter have been published in the literature. Tailoring the ureter before reimplantation can be performed extracorporeally by dissecting the entire length of the ureter and dividing it at the distal end. The distal 5–7 cm of the ureter can then be delivered extracorporeally and tapered to the right size. It is then dropped back into the abdomen and reimplanted to the bladder in a nonrefluxing manner [17]. Agarwal *et al.* reported a technique utilizing a traction suture/vessel loop to provide a firm anchor to the ureter without dividing it from the bladder and thus aiding intracorporeal tapering [18]. These techniques can be easily adapted to the robot, as published by Hemal *et al.* [19].

Minimally invasive bladder and bowel continence procedures and bladder augmentation procedures

The role of bladder and bowel catheterizable channels to achieve continence and bladder augmentation for a poorly compliant bladder are well-established procedures in pediatric urology. The nature of these procedures demanded a significant sized open incision and hence these were ideal candidates for utilizing minimally invasive techniques like laparoscopy and robot-assisted laparoscopy. The first report using a minimally invasive procedure was by Jordan *et al*. [20]. They reported the laparoscopic creation of an appendicovesicostomy in a child with an obliterated bladder neck. Multiple reports have since been published on minimally invasive bladder reconstruction for augmentation and continence.

Procedures and outcomes

In spite of differences in technical details, most authors have chosen to use laparoscopy to mobilize the bladder and bowel, and to perform cystotomy and the final augment anastomosis to the native bladder. The bowel loop isolation, detubularization, and augment creation were performed extracorporeally. Hedican *et al*. in their series of eight patients in 1999, reported use of laparoscopy to perform a variety of procedures [21]. These included six patients who had bladder augmentation performed using extracorporeal reconstruction through a Pfannensteil incision or an existing midline scar. They felt that the scars were substantially smaller than when the entire reconstruction was performed in an open fashion. The same group later reported the early and long-term outcome with 7-year follow-up in 31 patients who had undergone laparoscopic reconstructive procedures [22]. Not all these patients were children (median age 14 years, range 1–36 years). In terms of operative and perioperative outcomes, there was one conversion to an open procedure secondary to dense adhesions. A variety of procedures were performed including appendiceal vesicostomy, Malone antegrade continence enema (MACE) channel creation, and bladder augmentation, with a total of 39 stomas and 16 bladder augments

created in 29 patients. Early complications occurred in five patients and included bowel obstruction, deep vein thrombosis, and ileus. The median hospital stay in these patients was 6 days. On long-term follow-up, they found stoma revisions had been performed in 7.7% with a stomal stenosis rate of 5.5%, which is in line with the open experience.

In the largest series of laparoscopic bladder augmentation published to date, El-Feel *et al*. reported a mean operating time of 202 min and a mean hospital stay of 5 days [23]. Two patients had long-term complications unrelated to the surgical technique. They argued that the bowel anastomosis and the detubularization of the bowel is best performed extracorporeally, while others have reported that the entire procedure can be performed intracorporeally [24 –26].

To assess if there is really a benefit in performing laparoscopy in a patient who still requires an incision, albeit small, for the extracorporeal part of the procedure, Caddedu *et al.* compared open surgery with laparoscopy-assisted surgery [27]. In their study, the operative time and complication rate were comparable between the two groups. However, the time to return to regular diet and hospital stay were significantly shorter in the laparoscopy-assisted group when compared to patients who underwent open surgery. It is important to mention that neither of these groups included patients having bladder augmentation, and primarily consisted of patients undergoing MACE and Mitrafanoff procedures.

It would be a mistake not to mention the role of robot-assisted surgery in these days of rapid adaptation to new techniques. Totally laparoscopic augmentation of the bladder is tedious and time-consuming, mainly because of intracorporeal suturing. Robotic assistance makes this part easier to perform and hence might have a role to play in bladder augmentation procedures of the future. The first report using the robot to perform bladder augmentation in a child was published by Gundeti *et al*. from Chicago in 2008 [28], with excellent outcomes. Although this procedure lasted for 10 h, the authors should be commended for their effort. It can be hoped that with experience, the operating time will come down with retention of the benefits of minimally invasive surgery.

Minimally invasive approach for urachal remnants

Persistence of part of or the entire allantois can present in children with a patent urachus. By the fifth month of gestation, the urachus is nearly obliterated to ligamentous structure with an obliterated lumen lined by epithelium and an outer fibromuscular layer. This fibromuscular band then eventually becomes the median umbilical ligament. Depending on the part of the urachus that is persistent, patients may present with an urachal fistula, urachal umbilical sinus, vesicourachal diverticulum or urachal cyst (most common anomaly). Although these anomalies are seen in half of fetal specimens and persist in 2% of adults, they seldom become symptomatic [29]. If these anomalies do become symptomatic, they can present with infection or drainage. These symptoms are often persistent and recurrent and hence need surgical correction. It is well established that these lesions are at risk for developing adenocarcinoma later in life and this is another reason for surgical intervention. Surgical repair has traditionally been done in an open fashion, but laparoscopy can provide a minimally invasive approach to correct these anomalies.

Urachal remnants were first described and treated by Bartholomaeus Cabrolius in 1550 and since there have been multiple reports on their open surgical management [30]. Tronsden *et al.* in 1993 described the first laparoscopic approach to the excision of urachal remnant [31]. Since then multiple case series have been reported and show this technique to be a feasible and safe option for the surgical management of urachal remnants, even in children [32–36].

Surgical technique

Initial reports were of this technique performed in adult patients, and later in children. Although the surgical principles are the same in most of these reports, the optimal port placement has undergone a transition to laterally placed ports from cranially placed ports, particularly in children, to provide a better view of the urachal remnant. In the largest series of laparoscopic treatment of urachal remnants in 27 children, Turial *et al.* considered that the lateral approach provided a better visualization of the operative field [36]. A 5-mm laparoscope (alternatively a 1.9-mm scope) is placed in the left lateral aspect of the umbilicus, lateral to the rectus muscle. Two more ports are placed on either side of this camera port. The left medial umbilical ligament has to be divided to provide a clear view of the urachal cyst. The umbilical end of the urachal remnant is cauterized and divided. The bladder end is taken with or without bladder cuff as appropriate and the bladder sutured closed as needed. A Foley catheter in the bladder makes it possible to easily delineate the bladder and check closure after repair. Alternatively, the laparoscope can be placed either cranial to the umbilicus in the midline or in the lateral edge of the rectus fascia. The potential disadvantages of this are the proximity of the camera to the urachal lesion.

The laparoscopic approach has been universally found to be a safe and reliable technique to surgically correct urachal remnants. In adults, adenocarcinoma

arising in urachal remnants has been successfully treated with laparoscopy. In the largest series in children by Turial *et al*., median operative time was 35 min with no complications [36]. Postoperatively, the children did not have any complications with a median follow-up of 7 months. It has been utilized as a one-stage approach even for infected urachal cysts with excellent results [36]. According to these authors who used a 2–5-mm camera and 2-mm instruments, laparoscopy provided a superior cosmetic outcome and early recovery. Other authors have also concluded, although not from comparative studies, that laparoscopy provides earlier recovery and better cosmetic outcomes [34].

Minimally invasive genitoplasty

Children born with congenital absence or hypoplasia of the vagina in isolation (Mayer–Rokitansky–Kuster–Hauser syndrome) or in association with other anomalies, like disorders of sexual development or genitourinary development, should be considered for vaginoplasty. A good preoperative work-up is necessary to accurately diagnose this condition and define appropriate treatment. Most experts in this field agree that gradual vaginal dilation should be the first step in the management of these children [37]. If this is unsuccessful, then surgical reconstruction is considered. The timing of reconstruction is controversial and the recent impetus has been to perform these procedures during adolescent or early adult life due to better psychologic acceptance by these age groups [37].

Several different techniques of open vaginoplasty have been described in the literature, including the Vecchietti procedure, Davydov procedure, and intestinal vaginoplasty. All these techniques have recently been adapted to laparoscopic technique with good results, although the experience is still early. Although a detailed explanation of the various surgical techniques is beyond the scope of this chapter, we will attempt to provide an outline, as well as evidence for the feasibility of the minimally invasive approach.

Laparoscopic Vecchietti procedure

The principle of the Vecchietti procedure is traction from inside rather than dilation. The procedure involves placement of an acrylic ball in the superficial surface of the vaginal dimple. This is connected by wires under tension that pass through the vaginal dimple into the abdominal cavity and out through the anterior abdominal wall to a tightening device. The wires are placed under laparoscopic guidance and passed through the vaginal dimple and attached to the acrylic ball. Traction is applied to the vaginal dimple by gradually tightening these wires and elongating and enlarging the vaginal vault. Laparoscopy was utilized as early as 1992 by Gauwerky *et al.* [38]. A retrospective comparative study by Borruto *et al.* found that laparoscopy was equivalent to traditional approaches in terms of outcomes (neovaginal length 74.9 mm vs 73.7 mm) and complications (0% vs 13%) [39]. Fedele *et al.* reported excellent long-term functional results in 110 patients who underwent the laparoscopic Vecchietti procedure [40].

Laparoscopic Davydov technique

The Davydov technique involves the creation of a neovaginal space and then the use of the patient's own peritoneal lining to cover the space. The large bowel serosa is tacked on the abdominal side to the peritoneum anteriorly to close the neovaginal space from the abdominal cavity. The neovaginal space can be created by making a U-shaped perineal flap and bluntly dissecting between the bladder and the rectum. Laparoscopy has been utilized to mobilize the peritoneum and capping the neovagina with bowel serosa. Fedele *et al.* published their experience with the laparoscopy-assisted Davydov procedure in 30 patients, the largest series to date [41]. They found an excellent 95% anatomic success rate and 96% functional success rate at 6 months. Although their follow-up is short and this is still early experience, these are very promising results.

Intestinal vaginoplasty

Intestinal vaginoplasty involves harvesting a segment of bowel and using this segment to create a neovagina. Surgeons have used ileum or colon for this procedure [37, 42, 43]. Recently, the da Vinci robotic system was used to perform this procedure in a 17-year-old patient [44]. Laparoscopy was utilized for bowel mobilization, segmental resection, and re-establishment of bowel continuity. Two large series from China, one using ileum [42] and the other using colon [43], have both reported excellent safety and feasibility, with excellent postoperative functional outcomes.

Conclusions

Laparoscopy is an excellent minimally invasive option to surgically correct urachal remnants in children. This technique can be utilized even in children with an infected urachal cyst. It is a safe and reliable technique with possible but not proven better recovery and cosmetic appearance compared to open surgical repairs.

Laparoscopy is in its infancy with regards to reconstructive bladder and lower urinary tract surgery, particularly in children. Most reported experiences have been for older children or young adults. We hope that more experience and concomitant technologic

innovations will push the frontiers in minimally invasive surgery and bring its benefits to children needing urologic reconstruction.

CHAPTER 99
Laparoscopic Management of the Undescended Testicle

Lane S. Palmer
Albert Einstein College of Medicine and Cohen Children's Medical Center of New York, North Shore – Long Island Jewish Health System, Long Island, NY, USA

Introduction

Prior to the advent of laparoscopy, the gold standard for localizing and managing the nonpalpable testis was open surgical exploration. This surgery began with an inguinal incision that was extended so as to access the retroperitoneum if a testis, nubbin or blind-ending vessels was not identified. In cases of bilateral nonpalpable testes, a Pfannenstiel incision was not uncommon. If a testis was identified, an orchidopexy or orchiectomy was performed depending on its perceived viability. While the success rate of this approach was acceptable, the approach began to change in 1976 when Cortesi *et al.* described the laparoscopic identification of an intra-abdominal testis [1]. Subsequently, there was confirmation of the safety and utility of diagnostic laparoscopy. The next evolutionary step came with the reports of therapeutic laparoscopy (orchidopexy and orchiectomy) by Bloom [2], Jordan *et al.* [3], and Bogaert *et al.* [4]. Today, laparoscopy has largely replaced open surgery for evaluating and managing the nonpalpable testis. The benefits of the laparoscopic approach over the open approach are seated in its superior accuracy for localizing the testis and its minimally invasive nature to achieve superior surgical results for testis viability and position.

Epidemiology

Cryptorchidism is a common congenital anomaly present in about 3% of full-term newborn boys [5–8]. The testis may be present in the abdomen or be palpable anywhere along the normal path of descent. Cryptorchidism is more commonly unilateral than bilateral (1.6–1.9%) and is more common among the premature (30.3%), suggesting that testicular descent may not be complete until near term [5]. Low birth weight is a particular risk factor for cryptorchidism, which affects 7.7%, 2.5%, and 1.4% of boys weighing under 2000 g, 2000–2499 g, and over 2500 g at 3 months [6]. The simultaneous presence of hypospadias and cryptorchidism occurs more commonly than would be predicted [9], and a diagnosis of a disorder of sexual differentiation needs to be entertained. There is a familial predisposition to cryptorchidism as the risk to a newborn male is 6.9-fold if he has an affected brother and 4.6-fold if he has an affected father [10, 11].

Testes may continue to descend postnatally into the scrotum [7, 11]. Wenzler *et al.* found that 70–77% of cryptorchid testes descended spontaneously, usually by 3 months of age, and only 6.9% of testes descended after 6 months of age [12]. While the exact cause of cryptorchidism is unknown, birth weight alone appears to be a principal determinant independent of the length of gestation [13–15]. The incidence of cryptorchidism is 1% by age 1 year and remains constant throughout adulthood.

Classification and implications

The simplest way to classify cryptorchidism is to stratify the position of the cryptorchid testis based on physical

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

examination as either palpable (distal to the internal inguinal ring) or nonpalpable (intra-abdominal) [16]. Approximately 80% of cryptorchid testes are palpable and 20% are nonpalpable. Among the latter group, about 50% of boys will have an intra-abdominal testis. The intra-abdominal testis is usually located a few centimeters proximal to the internal inguinal ring, although it may be present anywhere between the ring and the lower pole of the kidney. The "peeping" testis lies at the entrance of the internal inguinal ring and can move between the abdominal cavity and inguinal canal. The nonpalpable testis is intra-abdominal (as described above), absent (vanishing) or atrophic. The absent (vanishing) testis is diagnosed at exploration when blind-ending spermatic vessels are encountered proximal to the internal inguinal ring. Atrophic testes are smaller than normal and may be found anywhere along the course of normal descent: intra-abdominal to scrotum.

Cryptorchidism predisposes men to subfertility and testicular cancer. Unilateral cryptorchidism may impair fertility in 50–70% of boys and 75% of those born with bilateral cryptorchidism despite orchidopexy [17]. Despite greater histologic deterioration with higher testicular position, and accordingly worse fertility, paternity may be similar in both abdominal and extra-abdominal unilateral undescended testes [18]. Instead, reduced serum levels of inhibin B (reflective of Sertoli cell function and seminiferous tubule integrity) may better predict impaired spermatogenesis [19]. Men with a history of cryptorchidism are about 10 times more likely to develop testicular cancer over the general population. While orchidopexy may not reduce the risk of testicular cancer, the scrotal position allows for easier examination and perhaps earlier detection [20]. Moreover, it may improve fertility or diminish the potential for malignant transformation.

Evaluation of the nonpalpable testis

History

The evaluation of the child with cryptorchidism starts with a thorough history, which should include questions regarding the pregnancy (including the use of steroids), initial physical findings at birth, change in position or palpability of the testes, medical and previous surgical history, and also a family history of cryptorchidism or syndromes.

Physical examination

The best physical examination for the testes requires a cooperative and relaxed child. The examination starts with the child in the supine position but other positions, such as frog-legged or squatting, may be more useful at times to relax the cremaster muscle of the spermatic cord. Notation should be made of any penile abnormalities (hypospadias, ambiguous genitalia), scrotal symmetry or underdevelopment, and the inguinal canal for a bulge consistent with the presence of the testis. The room and examiner's hands should be warm, and the child should be made aware of the impending palpation. The fingers are swept from the area above the internal ring down along the inguinal canal and then into the scrotum. The testis might be palpable under the fingertips or it may snap back into the abdomen. Soapy water may facilitate the examination by reducing friction between the child's skin and the examiner's fingers. The size of the solitary palpable testis has been offered as a harbinger of monorchidism by several authors who found that a contralateral testis length of greater than 2.0 cm represented compensatory hypertrophy [21–23]. The limitation of performing a physical examination in a child is highlighted by Cisek *et al.* [24], who found 18% of "nonpalpable" testes to be palpable during physical examination under anesthesia and that 12.6% of viable testes were distal to the inguinal canal.

Imaging

It is not possible to advocate for routine use of any imaging modality to localize a nonpalpable testis without confirmation by some means of exploration [25–29]. Ultrasound is commonly ordered to localize the nonpalpable testis; however, it rarely localizes a true nonpalpable testis and only identifies 18% of intracanalicular testes [30]. Magnetic resonance imaging (MRI) and gadolinium-enhanced magnetic resonance angiography carry higher sensitivity [31], but are less accurate than laparoscopy, expensive, and require anesthesia. In select cases, imaging may be helpful for patients at significantly increased risk of general anesthesia. In addition, should imaging identify a structure deemed to be a testis, surgical exploration is indicated for confirmation of its presence, as well as to determine whether the testis is viable or dysmorphic/hypoplastic and to identify nonunion abnormalities, neither of which can be properly determined radiologically

Hormonal therapy

Various protocols have been offered using gonadotropin-releasing hormone (GnRH), human chorionic gonadotropin (hCG)-β or testosterone to stimulate testicular descent. The basis for this approach stems from experimental observations that testicular descent is androgen mediated [32]. hCG directly stimulates Leydig cells to produce testosterone, while GnRH stimulates luteinizing hormone (LH) release by the pituitary, which promotes testosterone production. Successful descent is

more common in older boys and in retractile testes or those distal to the external inguinal ring [33, 34]. Hormonal therapy is rarely therapeutic in cases of nonpalpable testes; however, occasionally the testis may descend to a palpable position which changes the surgical approach. Occasionally, nonpalpable testes can fully descend [35]. This option is best applied to boys with bilateral nonpalpable testes.

Surgical management

Timing

The current recommended timing for orchidopexy is between 6 and 12 months of age. This recommendation is based on several considerations including: (1) histologic evidence of impaired germ cells after 18 months of life [36, 37]; (2) spontaneous testicular descent may occur in the first 6 months; (3) testicular growth is more common in children operated on before age 18 months compared with those operated on at an older age [38]; (4) early orchidopexy enhances adult Leydig cell function [39]; and (5) anesthesia risks decline after age 3 months.

Diagnostic laparoscopy

There are significant implications of leaving an intra-abdominal testis in place, particularly with respect to a delayed diagnosis of malignancy. Therefore, the primary goal in these children is to identify the presence or absence of a viable testis. Radiologic imaging is insufficiently sensitive to localize the gonad and incapable of assessing viability. In contradistinction, diagnostic laparoscopy is safe [40], carries an accuracy rate greater than 95% [41, 42], and can identify testes that have previously been deemed absent by open exploration [43, 44].

Surgical technique

The child is placed supine after administration of general anesthesia. The surgeon may choose to frog leg the lower extremities to facilitate access to the scrotum and to tuck the arms rather than to extend them on boards that may interfere with positioning of the surgeon's body during laparoscopy. The patient should be prepared and draped from above the umbilicus to the mid thighs and laterally to the side walls. The monitor should be placed at the foot of the table.

Diagnostic laparoscopy begins by either blind passage with a Veress needle or direct open access to the abdominal cavity. The abdominal skin is grasped to elevate the umbilicus and the Veress needle passed by puncturing the umbilicus. Entry into the abdominal cavity can be tested by ascertaining negative aspiration with a syringe, a positive drop test, and very low intra-abdominal pressure measurements. Subsequent to creation of pneumoperitoneum, a skin incision is made in the region of the umbilicus (vertical through the umbilicus or semilunar, either supraumbilical or infraumbilical) and the trocar is pushed or twisted (according to the nature of the bladed trocar) until the abdomen is entered. What has been described is a two-step procedure, with both steps requiring blind passage of instruments into the abdomen. Our preferred method for access to the abdominal cavity is the open technique which reduces the risk of injuring the intra-abdominal contents, particularly given the small distance between the abdomen and back in such small children. This approach begins with one of the skin incisions listed above and dissection down to the rectus fascia. A horizontal mattress suture of 3-0 polyglactin is placed into the fascia at this point, which facilitates closure. The rectus fascia is then opened in the middle of the horizontal mattress suture and the properitoneal fat spread to expose the peritoneum. The peritoneum is grasped with atraumatic forceps and then with two small mosquito clamps after ensuring that bowel has not been grasped. The peritoneum is them opened sharply and a 5-mm trocar inserted into the abdomen (Figure 99.1). Insufflation of the abdomen is accomplished using carbon dioxide at flow rates of 8–10 L/min to achieve a pressure of 8–10 mmHg. There are several adjunctive maneuvers to improve visibility in the pelvis: aversion of nitrous oxide by the anesthesiologist which may distend the small bowel; placement of a rectal catheter to reduce air in the rectum; placement of a urethral catheter to empty the bladder; and placing the table in Trendelenburg position to draw the bowel cranially.

Inspection of the pelvis is best performed with a 30° lens. The bladder should be positioned in the center of the operative field between the paired median umbilical ligaments and the urachal remnant noted at the dome running cranially toward the umbilicus. The presumed normal contralateral side should be inspected first as a basis for comparison of the affected side. The vas deferens is seen coursing from the pelvis on either side of the midline, crossing over the median umbilical ligaments towards the corresponding internal ring. The internal inguinal ring is identified from the convergence of the spermatic vessels with the vas deferens on the nonaffected side. There should be inspection for an open contralateral internal inguinal ring and if noted, this can be corrected laparoscopically at the same setting [45]. Caudal traction on the descended testis can help visualize the cord structures. Inspection of the internal ring on the affected side will show one of the following scenarios (Figure 99.2):

- An intra-abdominal testis attached to normal vessels and vas with an open or closed ring. The processus

Figure 99.1 Example of a 5-mm port placed in the umbilicus through a vertical incision. This port is used for the 30° lens laparoscope for either diagnostic or therapeutic laparoscopy.

vaginalis may be patent and a long-looping vas deferens may descend through the open ring into the inguinal canal. In many cases of an open inguinal ring with normal appearing vessels and vas deferens, the testis will be seen within 1 cm of the ring. The internal inguinal ring may be closed and the testis located more proximally along the course of descent in the area of the kidney or may cross-over ectopically. Thus, the entire abdomen should be inspected if the testis is not apparent. If the left colon or cecum is hiding the testis, additional ports may be needed for proper dissection and confirmation of the presence or absence of the testis.

- Cord structures entering the internal ring that may indicate gonadal tissue distal to the ring. If the testis is peeping into an open ring, it can be pushed into the abdomen by massaging the canal. If spermatic vessels and vasa pass through the internal ring, a search for viable testicular tissue should be undertaken. Although atretic vessels are associated with nonviable testicular tissue, De Luna *et al.* found residual tubules in approximately 10% of remnants, of which 5.6% contained germ cells [46].
- Vessels ending blindly proximal to a closed internal ring without attached testicular tissue. A vanishing testis due to vascular compromise can only be confirmed by finding blind-ending vessels and not just an atretic vas deferens, although the latter is commonly associated with blind-ending vessels. Approximately 36–64% of children with a nonpalpable testis will be monorchid [24, 42, 47–50].
- A blind-ending vas seen without testicular vessels in the vicinity of gonadal disjunction. The laparoscopic exploration should continue cranially toward the origin of the testicular vessels until the gonad is located.

Diagnostic laparoscopy will determine whether a testis or testes are present in the abdomen. In nearly 50% of cases, no testis will be found; the vanishing testis syndrome [24, 51]. The surgeon must determine the viability of the gonad(s) and whether orchidopexy or orchiectomy is indicated. If orchidopexy is to be performed, then the need for a Fowler–Stephens procedure must be determined (ideally before surgical intervention is initiated). Another potential finding is the presence of a gonad distal to the internal inguinal ring that was not found on physical examination and requires further exploration and management. Once diagnostic laparoscopy has established the clinical landscape, the decision to transition to therapeutic laparoscopy or open surgery can be made based on surgeon experience and comfort.

Diagnostic laparoscopy poses few complications. Subcutaneous emphysema and hematoma are minor problems that seldom cause abortion of the procedure. The potential for major complications such as injury to vessels and intra-abdominal organs is rare using an open technique for access. The risks during therapeutic laparoscopy are similar to those for diagnostic laparoscopy, except for greater potential to injure adjacent organs and structures. Hsieh *et al.* reported three bladder injuries among 101 laparoscopic orchidopexies [52]. They recommended establishing the border of the bladder by modulating the volume of fluid in the bladder via a urethral catheter; careful perivesical dissection, particularly in boys with prior inguinal surgery; and maintaining a high index of suspicion, particularly in the presence of hematuria.

Laparoscopic orchidopexy

Laparoscopic orchidopexy was first described in 1992 by Jordan *et al.* [3], who then described the laparoscopic staged Fowler–Stephens procedure in 1994 [53]. Since then, several thousand cases have been described, reporting excellent success rates, often superior to reported open surgical cases. Docimo conducted a meta-analysis of open surgical orchidopexy and found an overall success rate of 76.1%: transabdominal orchidopexy 81%; single-stage Fowler–Stephens orchidopexy 67%; and two-stage Fowler–Stephens orchidopexy 73% [54]. In comparison, Baker *et al.* reported on a multi-institutional compilation of laparoscopic orchidopexy cases and found a 97.2% success rate for non-Fowler–Stephens orchidopexy, 74.1% for one-stage Fowler–Stephens orchidopexy, and 87.9% for two-stage Fowler–Stephens orchidopexy [55]. The atrophy rate was 6.1% for all cases and only 2% for the non-Fowler–Stephens cases. The single-stage Fowler–Stephens orchidopexy carried a higher atrophy rate (22%) that the two-stage procedure (10%). Comparing these two

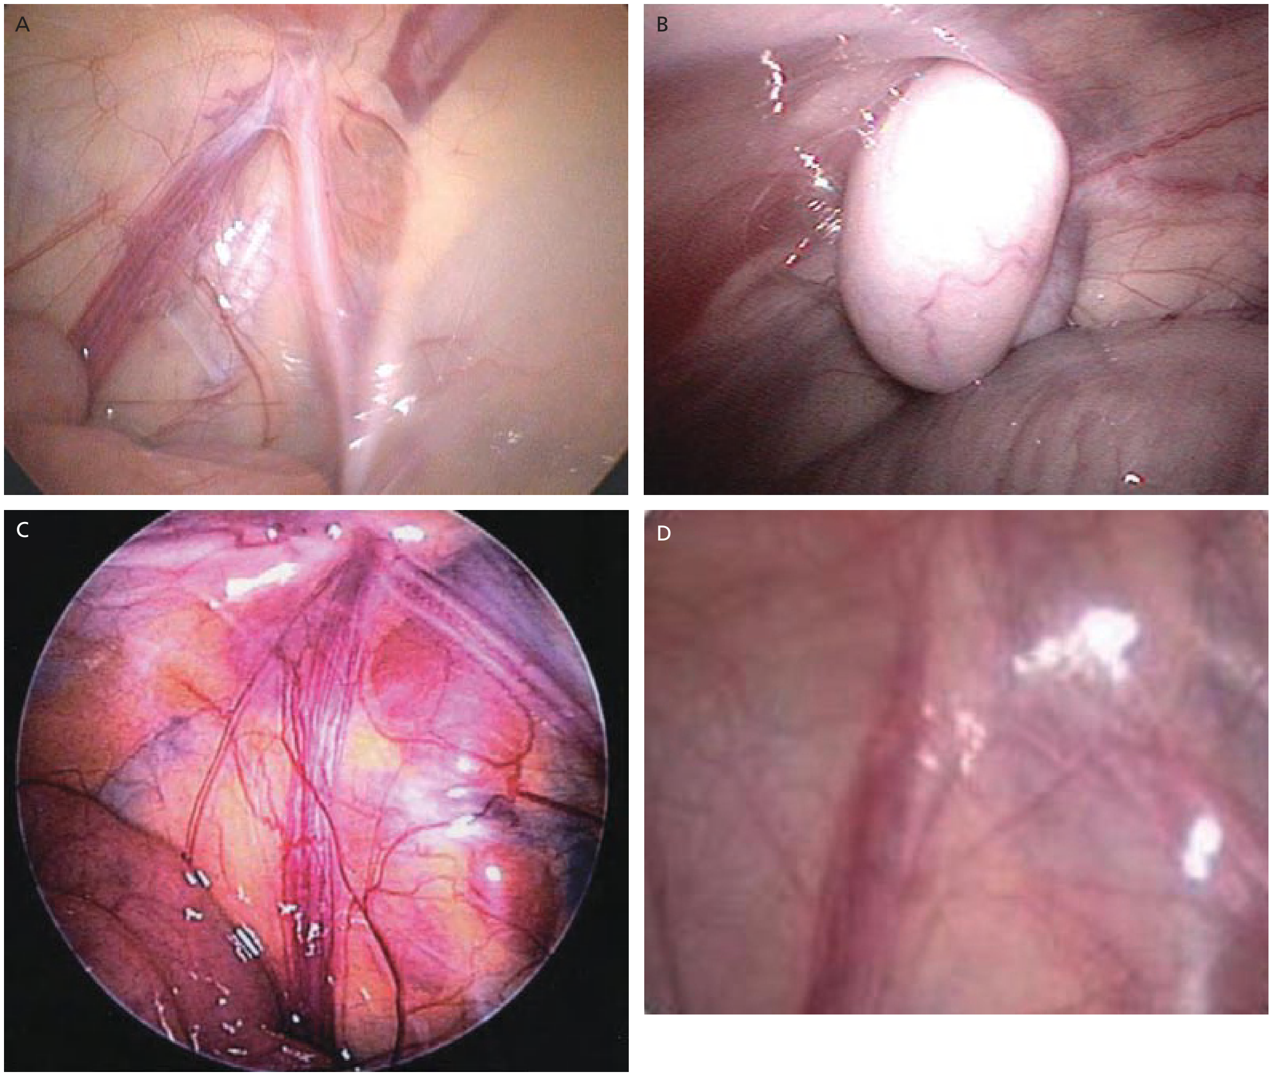

Figure 99.2 Laparoscopic views of the pelvis in the area of the internal inguinal ring. (A) Normal closed internal inguinal ring with healthy vessels and vas deferens. (B) Intra-abdominal testis subtended by normal internal spermatic vessels and vas deferens. (C) Vas and atretic vessels entering into a closed internal inguinal ring. Scrotal exploration identified an atrophic nubbin with visible hemosiderin. (D) Blind-ending spermatic vessels and vas deferens consistent with vanishing testis syndrome.

studies, laparoscopic orchidopexy yielded superior results to open orchidopexy regardless of the specific technique used. Unfortunately, long-term data are sparse but Esposito *et al.* reported on 12 patients with at least 10-year follow-up who underwent a two-stage laparoscopic Fowler–Stephens procedure [56]. The operated on testis was always smaller than the normal testis, despite good vascularization on Doppler ultrasound in 10 testes (83.3%); two (16.7%) testes were atrophic.

The success of this procedure is predicated on the final position of the testis in the scrotum and its viability. A satisfactory position is generally considered to be dependent in the scrotum which facilitates later physical examination. Viability reporting generally reflects the subjective opinion of its author. Causes of atrophy include maintenance of the testis on tension after fixation, skeletonization of the vessels, significant vasal dissection, and delayed ligation of the internal spermatic vessels because of inadequate length. Lindgren *et al.* reported an overall 93% success rate and no cases of testicular atrophy when either primary or Fowler–Stephens laparoscopic techniques were used [57]. Chang *et al.* reported that prior surgery was a risk factor, again due to loss of collateral vessels [58]. In that same report, they reported an overall 85% success rate for all Fowler–Stephens procedures and a 4% atrophy rate. In a more recent report from the same group, Samadi *et al.* noted a 95% success rate among 203 laparoscopic

orchidopexies, and considered that this high success rate could be attributed to minimal manipulation of the testicle during dissection, a wider peritoneal window, and sparse use of electrocautery [59]. Dave *et al.* compared testis viability by Doppler after initial laparoscopic testicular vessel ligation followed by a second-stage Fowler–Stephens orchidopexy performed laparoscopically (61 testes) or open (12 testes) [60]. The atrophy rate was 20.5% in the laparoscopic group and 0% in the open group. None of the five testes with long-looping vas atrophied following open orchidopexy, while five of six (83%) atrophied after laparoscopic orchidopexy (P = .03). They concluded that perhaps the second-stage procedure should be performed in an open fashion to better preserve collateral vessels.

Surgical techniques (see Video 99.1)

The positioning of the child, preparation and draping, placement of adjunctive catheters, and anesthetic considerations are the same as those described above for diagnostic laparoscopy. Since therapeutic laparoscopy starts with a diagnostic evaluation, the placement of the umbilical port, insufflation considerations, and inspection are the same. The surgeon should stand on the contralateral side of the affected testis. The monitor is best positioned at the foot of the table. Once it is determined that a viable testis is present in the abdomen and that laparoscopic orchidopexy will proceed, two additional ports (3 or 5 mm) are placed. Radially dilating 5-mm ports allows the use of smaller incisions without compromising the use of small instruments, including a 5-mm clip applier if needed. The skin incision should accommodate the size of the ports and the subcutaneous tissue spread before placement of the ports. These ports should be placed under direct vision through the laparoscope in the umbilical port so as to avert injury to any intra-abdominal structures. The two working ports can be placed at the level of the umbilicus and the midclavicular line (Figure 99.3) or alternatively, a port ipsilateral to the intra-abdominal testis is placed below the subcostal margin and the second port is placed in the contralateral lower abdominal quadrant.

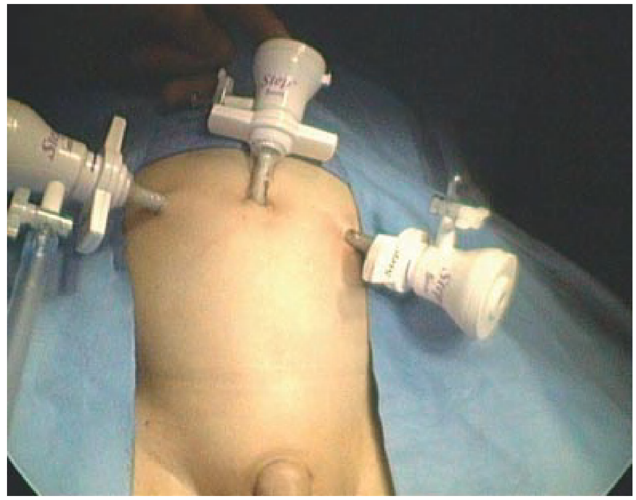

Figure 99.3 Port placement for laparoscopic orchidopexy in a child with an intra-abdominal testis. The two 5-mm ports are placed at the level of the umbilicus and the mid-clavicular line.

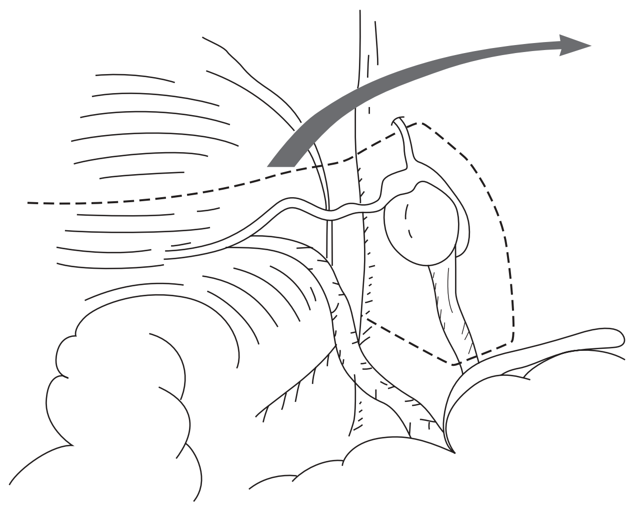

Figure 99.4 Lines of incision for the laparoscopic orchidopexy: lateral to the internal spermatic vessels, caudad to the vas deferens, and around the internal ring (reproduced from Chang, M., Franco, I. Laparoscopic Fowler–Stephens orchiopexy: the Westchester Medical Center experience. *J Endourol* 2008;22:1315–1319, with permission of Mary Anne Liebert).

Non-Fowler–Stephens orchidopexy

The peritoneal dissection can be divided into three parts that become continuous upon completion (Figure 99.4). The first peritoneotomy is made sharply lateral to the testicular vessels, and carried inferiorly to the inguinal ring and then superiorly as high as can be easily accessed, and when necessary, more proximally toward the origin of the vessels. The next incision is caudad and parallel to the vas deferens from the internal ring, and carried across the obliterated umbilical ligaments toward the bladder. Care should be taken to avoid deep dissection and inadvertent injury to the bladder or vessels of the umbilical ligament. Monopolar electrocautery should be used sparingly and at low current settings to avoid direct or collateral damage to vital structures. The peritoneotomies at the level of the inguinal ring should be connected. The third dissection involves drawing in the peritoneum that enters the internal ring (patent processus vaginalis), with care taken to avoid grasping a looping vas deferens. The gubernaculum is transected

using electrocautery or perhaps a LigaSure (Valleylab, Boulder, CO, USA) or Harmonic scalpel (Ethicon Endo-Surgery Inc, Cincinnati, OH, USA). This dissection leaves a triangle of peritoneum between the spermatic vessels and the vas deferens with the testis positioned at the apex.

Using the gubernacular attachment as a handle, the triangle of tissue (vessels, testis, and vas) is elevated cranially, taking care not to harm the external iliac vessels, inferior epigastric vessels or long-looping vas. A dissecting Kuttner or the backside of laparoscopic scissors can be used to tease the tissue off the vessels. To determine if there has been adequate dissection, the testis can be retracted towards the contralateral internal ring; in most cases, if the testis reaches beyond this point without traction, there is sufficient length to place it dependently in the scrotum. Any remaining attachments that retard the mobility of this pedicle should be released. If the extent of the dissection fails to provide sufficient length, additional dissection of the spermatic vessels should be performed toward their origin. Should additional length be needed, a relaxing incision of the triangle of peritoneum can be carefully made from the vessels to the vas deferens, which may significantly lengthen the vessels. Before making this incision, however, the surgeon must assess whether this maneuver will provide the required length; if not, it would be appropriate to consider a Fowler–Stephens procedure and divide the internal spermatic vessels and preserve the collateral vessels associated with the peritoneum. Ideally, the vessels should be transected before any of the above described incisions are made (see below).

The next step in the operation involves creating a neohiatus and delivery of the testis into the scrotum (Figure 99.5). In order to shorten the distance into the scrotum, a peritoneotomy is made lateral to the bladder and medial to the umbilical ligament, and this space is developed. A dissecting instrument is passed over the pubis and into the scrotum. A subdartos pouch is then created over the point of the dissector, which then is passed through the scrotal fat. Removing some of this fat can facilitate the next step, which is to pass a 5- or 10-mm trocar with a beveled end retrograde over the dissector and into the abdomen under direct vision. This trocar is easiest to pass if it is rotated through 360° while pushing, which negotiates it away from any intervening tissue. A locking grasper is then passed through the scrotal trocar to grasp the gubernacular stump. Once the proper orientation of the testis and cord is ascertained, the testis is drawn to the trocar and both are brought out to the scrotum. The gubernaculum is secured with a mosquito clamp and inspection is made to confirm proper orientation and laxity of the pedicle. Additional dissection is performed to gain length if the testis is not dependent in the scrotum. Once a tension-free dependent testis can be positioned in the scrotum, it is fixed in the pouch according to the surgeon's usual technique (Figure 99.6). Hemostasis of the operative field is evaluated under low intra-abdominal pressure. It is not necessary to close the ipsilateral internal ring as the area scars and clinical hernias do not appear to develop. The lateral ports are removed sequentially, the fascia closed with absorbable suture under direct vision, and the abdomen insufflated. Hemostasis should be assessed at the port sites. The abdomen is desufflated through the umbilical port and then closed with the horizontal mattress suture placed earlier in the operation. Before securing this stitch, it is important to ensure that the port sites are free of bowel and omentum. The port sites are closed subcuticularly and then dressed. Analgesia can be achieved by either caudal anesthesia or local injection of bupivacaine hydrochloride.

Single-stage Fowler–Stephens laparoscopic orchidopexy

As mentioned above, there are cases when the vessel length is found to be insufficient to allow the testis to reach the desired scrotal position. A single-stage Fowler–Stephens procedure can be performed where the testicular artery and vein are clipped and transected [alternatively, the vessels can be divided using a LigaSure (Valleylab) or Harmonic scalpel (Ethicon Endo-Surgery Inc], preserving the vasal blood supply to the testis (Figure 99.7). This frees the testis so that it can be placed in the scrotum. However, division of the testicular vessels is associated with higher atrophy rates.

Two-stage Fowler–Stephens laparoscopic orchidopexy

If diagnostic laparoscopy reveals a high testis that cannot reach the scrotum without transection of the testicular vessels, a two-stage Fowler–Stephens laparoscopic orchidopexy can be used. In the first-stage, a peritoneotomy is performed over the internal spermatic vessels proximal to the iliac vessels. The vessels are ligated using 5-mm vascular clips and then divided. Six months later, the testis is brought to the scrotum laparoscopically, based on the enhanced contribution of the paravasal vascular supply. The principles for the technique for the second stage of the procedure are as described for the non-Fowler–Stephens procedure above: peritoneal incisions are made lateral to the divided vessels and distal to the vas deferens; the triangle of peritoneum is developed, taking care to preserve all of the collateral vessels; the gubernaculums is divided; the pedicle is dissected off the posterior abdominal wall; and the testis brought into the scrotum through a neohiatus.

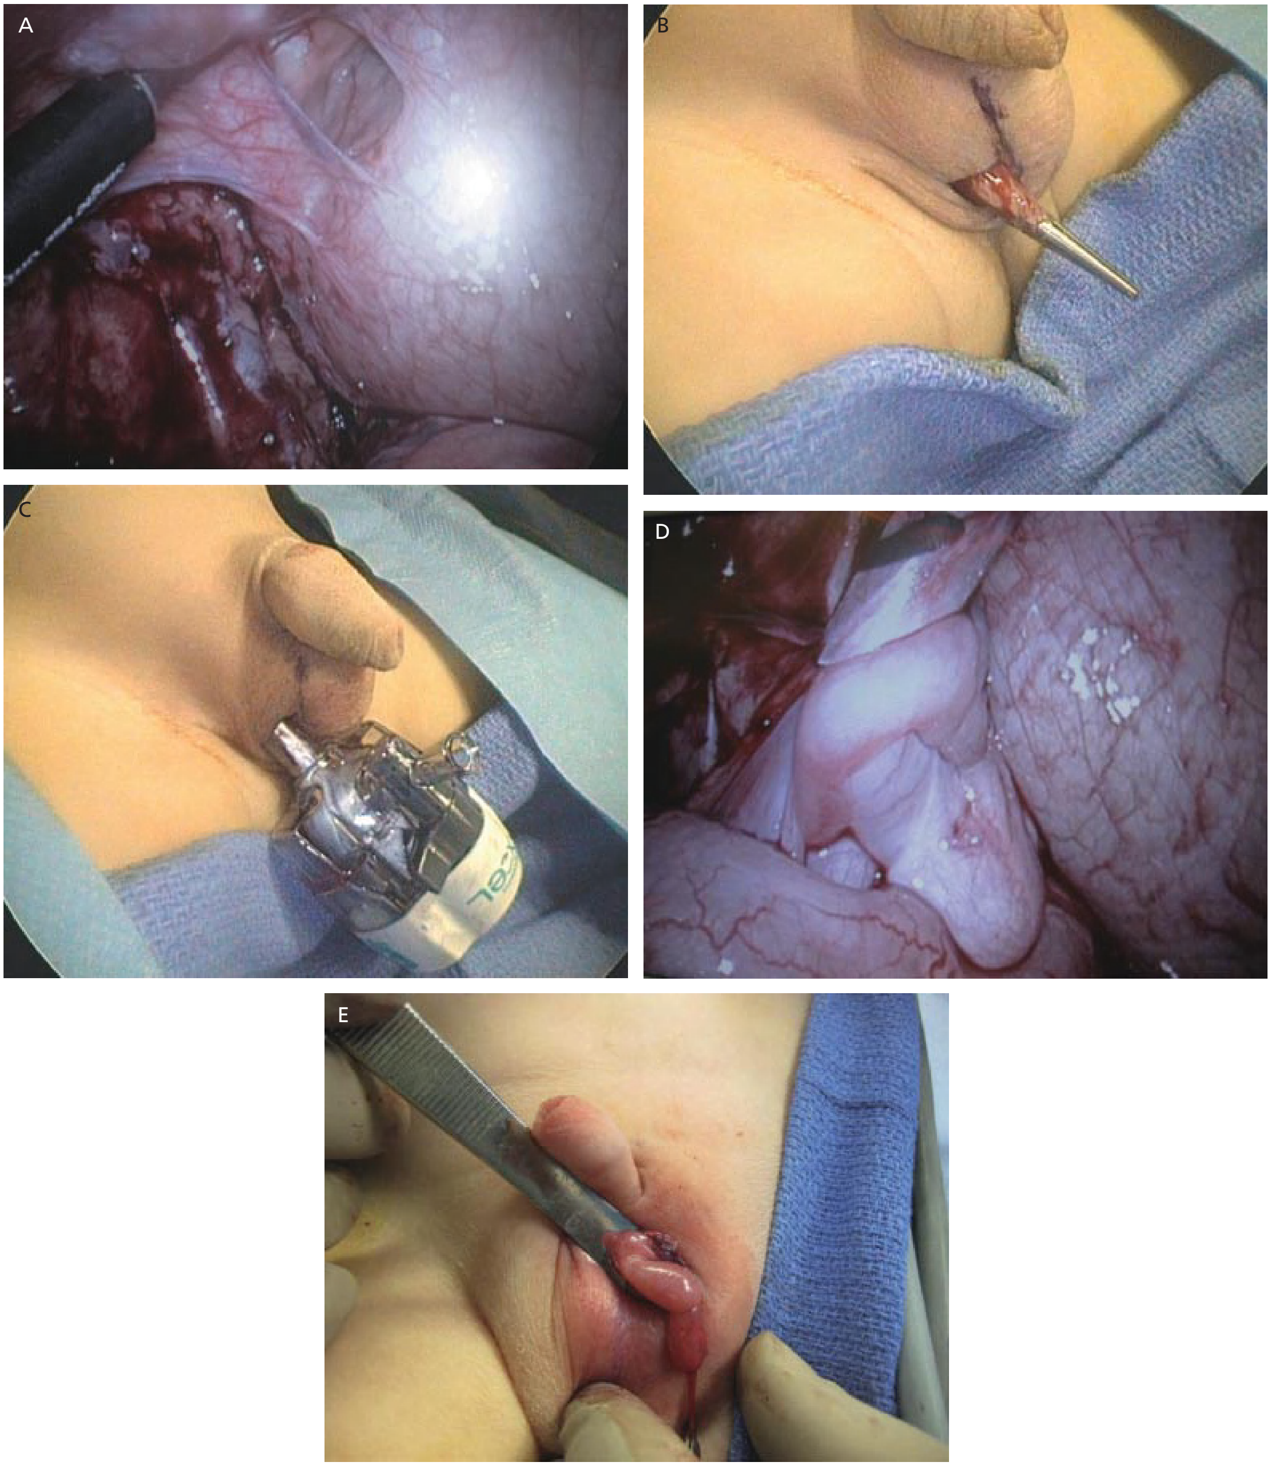

Figure 99.5 Development of the neohiatus and delivery of the testis. (A) Dissection between the lateral edge of the bladder and the medial aspect of the obliterated umbilical ligament. (B) Placement of the dissector through the neohiatus and over the pubis into the scrotum through the subdartos pouch. (C) A 5-mm port with a beveled end is passed retrograde from the scrotum, over the dissector, and into the abdomen. (D) The gubernaculum is firmly grasped through the scrotal port and the testis brought intrascrotal as the port is removed. (E) The testis is placed in proper orientation dependently into a subdartos pouch.

Bilateral intra-abdominal testes

The child with bilateral nonpalpable testes poses a more complex clinical situation. The issue of a disorder of sexual differentiation needs to be considered and evaluated. The work-up of such a child is beyond the scope of this chapter. However, once it is established that such a diagnosis is absent, the next step in management is to determine whether testes exist and then the number of testes that are present. In boys with anorchia, basal levels of gonadotropins [follicle-stimulating hormone (FSH) more than LH] will be elevated. If one or two testes are present and Leydig cell function is normal, then hCG administration should stimulate testosterone production. Nevertheless, inspection of the abdomen to determine the number of testes is necessary regardless of the outcome of the hCG stimulation test as false-negative studies are not uncommon. In a series from the Children's Hospital of Philadelphia, bilateral intra-abdominal testes comprised less than 1% of the total cryptorchid testes, but 3.1% of nonpalpable testes and 15.3% of all intra-abdominal testes [61]. Chang *et al.* reported that among intra-abdominal testes, 25% were bilateral [58].

Laparoscopy plays an important role in diagnosing bilateral intra-abdominal cryptorchidism and in surgical correction. Cortesi *et al.* in 1976 reported using diagnostic laparoscopy to successfully localize bilateral intra-abdominal testes in one patient [1]. Ansari *et al.* in 2002 reported on single-setting management of bilateral cryptorchidism in a 30-year-old man [62]. Kaye and Palmer specifically addressed the laparoscopic management of bilateral intra-abdominal testes in 26 boys (aged 7–52 months, median 9 months) [63]. A staged procedure was decided upon for five of these boys (four for very high positions, one for medical reasons to reduce operative time) before any dissection took place. Of the remaining 21 boys, 16 had successful single-stage bilateral laparoscopic orchidopexies to achieve viable intrascrotal testes at 1-year follow-up; two boys underwent two-stage Fowler–Stephens laparoscopic orchidopexy and one boy required a secondary open orchidopexy to achieve satisfactory intrascrotal position (total 91%). Surgery was free of complication and performed as an ambulatory procedure with minimal blood loss. The authors advocated bilateral single-stage laparoscopic orchidopexy when possible. The testis that appears best suited for successful orchidopexy should be operated on first and then a decision made to proceed with the

second testis. If viability of the first testis is questionable, then the authors advocated waiting about 3 months before proceeding with the second orchidopexy. If viability is not in question upon completion of the first orchidopexy, then the higher testis should be approached concurrently either as a single- or two-stage procedure (Fowler–Stephens) as indicated.

Conclusions

Laparoscopy has markedly improved the management of the nonpalpable testis. Diagnostic laparoscopy carries remarkable accuracy in determining whether a testis is present in the abdomen or whether the vanishing testis syndrome or an atrophic intra-abdominal testis exists. Although laparoscopy requires a 5-mm puncture and general anesthesia, the accuracy of this procedure exceeds that of the best imaging study, MRI, which also requires anesthesia, or open surgical exploration, which requires a larger incision as well as general anesthesia. Missing an intra-abdominal testis carries sufficient morbidity that accurate diagnosis is mandatory. Therapeutic laparoscopy in the form of orchidopexy can provide proper positioning of a viable testis more successfully than open surgery regardless of whether or not a Fowler–Stephens procedure is required. The laparoscopic approach allows for a better retroperitoneal mobilization and when ligation of the spermatic vessels is deemed necessary, can be done rapidly and simply with minimal incision and discomfort. Laparoscopic orchidopexy should be the procedure of choice for anyone familiar with laparoscopy. As current residents and pediatric urology fellows continue to incorporate laparoscopy into their training, open surgery for the nonpalpable testis will likely be relegated to historical interest.

CHAPTER 100

Laparoscopic Exit: Specimen Removal, Closure, and Drainage

Ricardo A. Natalin,[1] Jaime Landman[2] & Adam C. Mues[1]

[1]Columbia University Department of Urology, New York, NY, USA

[2]Department of Urology, University of California Irvine, Irvine, CA, USA

Introduction

Laparoscopic surgery has well-defined benefits for the patient and has, over time, become accepted as a standard of care access strategy for the management of benign and malignant urologic diseases. Exiting the abdominal cavity is an important step after all laparoscopic procedures and safe exit after laparoscopic surgery requires a systematic approach. At the conclusion of every operation, a careful inspection of the operative field must be performed in order to evaluate for adequate hemostasis and adjacent organ injury. Improper removal and closure of laparoscopic trocars or hand-assist devices can be a source for postoperative complications, such as delayed bleeding, dehiscence, or postoperative hernia, and can lead to unnecessary patient morbidity. A distinct advantage of laparoscopy is the ability to view extraction incisions and device closure defects following repair. This affords the surgeon the ability to rule out immediate problems with the closure, such as excessive bleeding and entrapment of visceral structures.

Despite significant advances in laparoscopic technique and technologies, laparoscopic urologic surgery remains technically demanding. Unlike open surgery, at the termination of laparoscopic extirpative procedures, the urologist is often faced with the additional challenges of specimen retrieval and extraction. Laparoscopic specimen entrapment and extraction occurs at what is falsely considered the "termination of the procedure." During open surgery, after the specimen has been mobilized, it is simply lifted out of the larger incision, which has been made to achieve the surgical objectives. At this time the open surgical team is typically more relaxed, and may turn up the volume on what is commonly referred to as "closing music." In contrast, significant laparoscopic skill is required to entrap and safely extract laparoscopic specimens. It is imperative that during laparoscopic procedures, the "termination of the procedure" be strictly defined as the termination of skin closure and dressing placement. Taking a few minutes to focus on safe specimen entrapment and extraction may substantially reduce major morbidity.

This chapter will outline a systematic approach for exiting the abdomen and focus on the technology and techniques of specimen entrapment, extraction, drainage, and various methods of abdominal wall closure. The primary objectives are to minimize morbidity while maintaining the advantages of a minimally invasive surgical approach.

Specimen collection and types of device

Laparoscopic specimen removal includes small dimensions from trocar sites (often smaller than the specimen extracted), making specimen retrieval and extraction very challenging. Currently, there are a number of commercially available retrieval devices that facilitate specimen extraction (Table 100.1). Important characteristics to be evaluated in a retrieval device are the sac permeability, resistance, and stability within the abdominal cavity [1]. Commercially available laparoscopic bag retrieval systems consist of single-use specimen collection bags

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 100.1 Laparoscopic specimen retrieval devices.

Device	Characteristics
LapSac® (Cook Urological, Spencer, IN, USA)	Made of nylon with polyurethane inner coating Requires 10–12-mm trocar for insertion Does not self-open Only sac with data to support use with intracorporeal morcellation
LapBag® (Bard-Angiomed, Salt Lake City, UT, USA)	Made of nylon with polyurethane inner coating Has special introducer for insertion Requires 10–12-mm trocar Self-opening sac
Extraction Bag® (Karl Storz, Tuttlingen, Germany)	Made with transparent polyurethane Special introducer for insertion Requires 10–12-mm trocar for insertion Self-opening sac
Endobag® (Covidien, Norwalk, CT, USA)	Transparent polyurethane Single use Requires 10–12-mm trocar for insertion Does not self-open
Endopouch® (Ethicon Inc, Somerville, NJ, USA)	Made of transparent polyurethane Single use Special introducer Requires 12-mm trocar Self-opening
EndoCatch® (Covidien, Norwalk, CT, USA)	Transparent polyurethane Special introducer Requires 10–12-mm trocar for insertion Self opening

that are sterile. These entrapment devices facilitate removal of the specimen without contamination of the abdominal cavity or extraction wound.

Collection devices

Pure sacs

Laparoscopic retrieval bags are primarily made of polyurethrane and are available in a variety of sizes. The bags are introduced through a trocar that is at least 10 mm in size using a blunt laparoscopic instrument. The bag is fully opened in the abdomen using blunt-tipped instruments so that the specimen can be properly introduced. Closure of the bag involves tightening the purse-string mechanism at the top of the bag in order to form a complete seal. Examples of this device include the LapSac (Cook Urological, Spencer, IN, USA) and the Endobag (Covidian, Norwalk, CT, USA).

Sacs with mechanisms

Retrieval bags such as the EndoCatch bag (Covidien) feature a polyurethane specimen bag collapsed within a long cylindrical tube, some of which can be introduced through a 10-mm trocar. The bag is deployed in the abdomen by opening a continuous metal ring that is attached to the top of the bag. The specimen is deposited inside the bag using blunt-tipped instruments and the purse-string mechanism is closed by pulling on the end of the suture, which is attached to a small plastic ring outside the body. This closes and seals the sac, and the string is cut in order to free the bag from the metal ring and introducing instrument.

Extraction incisions

Options at the termination of extirpative urologic procedures include intact extraction and specimen morcellation. For intact extraction, the specimen can be removed from the body through a variety of abdominal incisions. An extension of an existing trocar incision is often used, which prevents an entirely new incision from being created for removal. While expedient, extension of an existing trocar site should be done with caution as certain incisions are associated with higher rates of complications. Elashery *et al.* reported five of 29 with extraction site hernias after laparoscopic radical nephrectomy and extension of an existing trocar incision [2]. Tisdale *et al.* compared extraction sites formed

by an extended trocar site to a Pfannenstiel incision in patients undergoing laparoscopic radical nephrectomy, nephroureterectomy, and donor nephrectomy [3]. An incisional hernia developed in three (2.9%) patients who had an extension of a trocar site for extraction; no patients receiving a Pfannenstiel extraction developed a hernia. However, the closure method was not documented in either extraction site group. Bird *et al.* retrospectively analyzed patients undergoing laparoscopic radical nephrectomy and intact specimen retraction through three different incision sites (umbilical, paramedian, and lower quadrant) [4]. A total of 181 nephrectomies were performed. Four patients developed a hernia, all of which occurred through a paramedian incision. In addition, body mass index (BMI) was a significant factor related to the development of an incisional hernia.

Other extraction options include removal of the specimen through a new midline incision, which many surgeons prefer due to the familiarity with midline abdominal wall anatomy. Ideally, this approach is done with a small incision near the umbilicus (depending on specimen size), which is cosmetically more appealing. Specimen removal can also be performed through a low Pfannenstiel incision, which provides a good cosmetic result, but requires a new incision. The surgeon must plan in advance for this type of incision by ensuring that the patient is positioned adequately before the surgery, so that access to the lower abdominal wall can be obtained for specimen removal. When compared with an extended trocar extraction incision, Pfannenstiel incisions have demonstrated significantly less postoperative pain medication requirements (23.7 mg vs 47.3 mg morphine equivalent) and a reduced length of hospital stay (2.84 days vs 3.37 days) [3].

Specimen morcellation

Morcellation is the fragmentation of organs into smaller pieces, and is classically performed after the specimen has been entrapped and prior to removal in order to maintain a small abdominal wall incision. The practice, while an accepted standard of care, remains controversial, particularly for malignant disease. The primary goals of specimen morcellation are to safely maintain the minimally invasive nature of the laparoscopic approach and oncologic efficacy. However, controversy exists regarding patient safety and the quality of tissue to be examined for final pathology. In order to perform morcellation safely, the procedure must be done under direct endoscopic vision. Safe morcellation without tissue spillage or entrapment bag perforation is only typically done in the LapSac as it is the most durable entrapment sac, and it is the only entrapment sac which has been tested for impermeability [5, 6].

A technique of "modified morcellation" in which a 2.5-cm incision is used and the specimen is morcellated *ex vivo* under direct vision has been described. With modified morcellation, entrapment can be expedited and facilitated by the application of a less durable entrapment sac (described with the EndoCatch sac), and reasonable histopathology can still be gained due to the larger fragment size that can be achieved with this technique [7]. A limited number of case reports with tumor seeding and cancer recurrence have been reported after morcellation [8]. Possible contributing factors include using a retrieval sac that is not specifically designed for morcellation or unrecognized micro-perforations in the sac itself.

Another potential issue with specimen morcellation is the inability to accurately document pathologic tumor stage during an oncologic procedure. However, studies evaluating oncologic results of morcellation have shown that this technique did not significantly impact the ability to determine pathologic stage [9, 10]. In addition, recurrence rates were shown to be similar to those following intact specimen retrieval [11].

Systematic approach for exiting the abdomen after laparoscopic procedures

Step 1: Inspection

After completion of the surgical procedure, meticulous inspection of the surgical bed and surrounding structures is performed. Due to the limited haptic feedback associated with laparoscopy, it is essential that careful evaluation for hemostasis and adjacent organ damage is carried out. Organs and structures outside the surgical field can occasionally be damaged during surgical mobilization or retraction. In laparoscopic renal surgery, both the liver and spleen must be mobilized in order to gain perfect access to the kidney. The liver is often retracted cephalad using a locking–grasping instrument. Inspecting the entire surface of these organs is necessary to exclude injuries that may contribute to postoperative bleeding. Similarly, the colon and duodenum are mobilized medially. These bowel structures must be inspected following these maneuvers for potential lacerations or cautery injury. Laparoscopic procedures performed in the pelvis necessitate inspection of the small bowel, sigmoid colon, and pelvic vasculature to confidently rule out injury.

Following organ inspection, the surgical field must be examined for hemostasis. Although arterial bleeding is usually identified immediately, the pneumoperitoneum of 15–20 mmHg provides a venous tamponade effect that can obscure venous hemorrhage. Therefore, all portions of the surgical field must be examined under low insufflation pressure (≤5 mmHg).

Following a comprehensive evaluation of the abdominal and/or pelvic cavity, body wall access sites must be inspected for excessive bleeding. Trocars should be removed under direct vision and monitored briefly for the presence of bleeding. Special attention should be given to the trocar placed at the initial site of access as this is the only trocar that is not placed under direct vision. Bleeding from a trocar site can be controlled by placing an absorbable hemostatic suture (Vicryl or Dexon) at the trocar site with the aid of endoscopic vision. Other methods include the use of a Carter–Thomason device (Inlet Medical Inc, Eden Prairie, MN, USA). This device is also used for closure of the abdominal wall fascia and is described in detail later in this chapter. In most cases, bleeding from the abdominal wall can be controlled by these measures. However, if bleeding cannot be managed endoscopically, the trocar incisions should be extended at the skin level to allow for better access vision for proper hemostatic control.

If an extraction incision has been made for specimen removal, this incision should be endoscopically inspected to assure that no intra-abdominal contents have been incorporated into the closure and that there is no bleeding from this site.

Step 2: Trocar extraction, desufflation, and site closure techniques

Trocar site closure is dependent on both the size of the defect and the type of trocar used. Traditional "cutting" trocars have a sharp blade that penetrates the body wall, creating a defect in the fascia that is the same size as the diameter of the trocar itself. More recently, trocars that spread abdominal wall tissue and fascia ("dilating" trocars) create a defect by either axially or radially spreading the fascia. These "dilating" trocars create a fascial defect that is approximately half the diameter of the trocar. Therefore, even when 12-mm dilating trocars are placed, fascial closure is not necessary in healthy adults. In the pediatric population, all trocar sites should be meticulously closed regardless of the size or nature of the trocar being applied.

Shalhav *et al.* compared fascial nonclosure after the use of dilating trocars with fascial closure after the use of cutting trocars. No evidence of hernia formation occurred in either group at a mean follow-up of 4.8 months [12]. Liu and McFadden reported on results of 180 fascial sites after the placement of dilating trocars. After a median follow-up of 11 months, no hernias were documented [13]. Patients with poor quality fascia (history of abdominal wall herniation, steroid use, poor nutritional status) and pediatric patients should have all trocar fascial sites closed. While our team routinely leaves the fascia open after application of dilating trocars, we do perform a "digital inspection" (gentle palpation of the trocar site with a finger to assess the defect) to assure that the fascial defect has not expanded. If the fascial defect seems larger than usual, we do not hesitate to close the defect using the techniques described below.

Desufflation of the abdomen

Following the removal of all trocars under direct vision and prior to wound site closure, the abdominal cavity should be decompressed in order to eliminate the pneumoperitoneum. It has been suggested that residual gas in the abdomen may contribute to pain or ileus in the postoperative period. Desufflation is accomplished by removing all trocars and applying gentle pressure to the abdomen to expel the gas.

Closure techniques

Intracorporeal manipulation under direct visualization

The Maciol suture needle set (Core Dynamics Inc, Jacksonville, FL, USA) consists of a set of three needles: two black-handled suture introducers (straight tip and curved tip) and a gold-handled suture retriever. An absorbable suture is placed through the hole in one of the introducer needles, which is placed percutaneously through the abdominal wall while the trocar remains in place [14]. The retrieval needle is placed 180° from the initial suture passage and grasps the end of the suture. The straight introducer needle is assisted by a laparoscopic grasper in order to place the end of the suture into the retriever (Figure 100.1). Next, the trocar is removed and the fascia is pulled and tied together for closure.

The Grice needle (Ideas for Medicine Inc, Clearwater, FL, USA) is loaded with an absorbable suture and inserted at an angle along one side the trocar to be closed (Figure 100.2). A grasper is used from a different trocar to grasp the suture from inside the abdominal cavity. The Grice needle is then placed in the same manner along the other side of the trocar and the suture is regrasped with the Grice [14]. The Grice device with the grasped suture is pulled out through the abdomen and tied under direct vision.

Conlon *et al.* developed a method of closure using a 14G angiocatheter, which is placed on one side of the trocar defect [15]. Once this is visualized laparoscopically, the obturator can be removed and a 24-inch 0-absorbable suture is placed through the obturator and into the abdomen. The angiocatheter is then placed on the other side of the fascial edge. A 36-inch 0-absorbable suture is looped and placed through the catheter lumen. The initial free end of the suture is placed into the loop and the angiocatheter is removed. The suture is tied to itself, closing the defect (Figure 100.3).

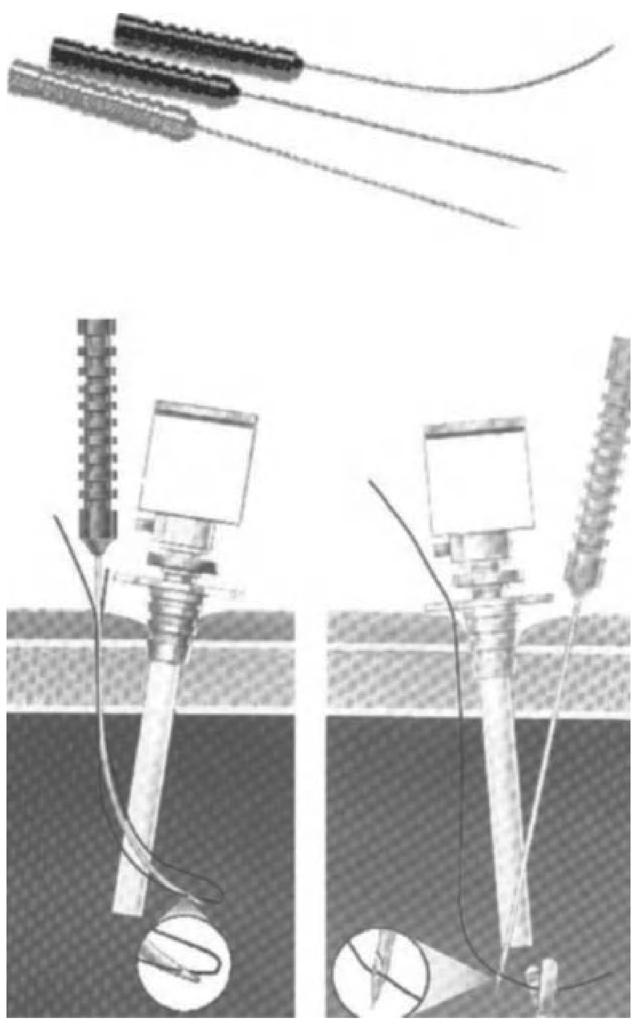

Figure 100.1 Maciol suture needle set (Core Dynamics Inc, Jacksonville, FL, USA) and technique (reproduced from Shaher [14], with permission).

The EndoClose suture device (Tyco Auto Suture International Inc, Norwalk, CT, USA) is a spring-loaded disposable device, which is loaded with a suture prior to being introduced into the abdomen in the gap between the trocar and skin edge. The suture is released and the device is placed 180° from the first pass. A grasper is used through a second port to place the suture in the open notch of the EndoClose device (Figure 100.4). The device is pulled out together with the trocar. The suture is then tied down to approximate the fascia.

Extracorporeal manipulation under direct visualization

The Carter–Thomason needle point suture passer (Inlet Medical Inc) consists of a cone-shaped plastic guide and the Carter–Thomason metal needle passer and grasper (Figure 100.5). The device is placed into the trocar defect initially. Next a 0-absorbable suture is placed in the needle passer, which traverses the abdominal wall and peritoneum through a hole in the top of the cone-shaped introducer. This process is performed under direct vision with the laparoscope during closure. The suture is then released and the grasper enters the abdomen through a second predrilled hole in the introducer. The suture is grasped and pulled out of the body and the suture guide is removed. Finally, the suture is tied, bringing the fascia together (Figure 100.6). Elashry *et al.* randomized 95 trocar-site closures to one of eight different types of closure devices. The Carter–Thomason was significantly faster than any other closure method (mean closure time of 2.5 min) with the exception of standard hand closure (1.9 min) [16]. This device also had no closure-related complications.

The Tahoe surgical instrument ligature device (Tahoe Surgical Instruments Co, San Juan, Puerto Rico) is disposable and includes a handle with a locking button and two hollow metal needles (2 cm apart) that are used for passing and retrieving sutures (Figure 100.7). The trocar is removed and the needles on the device are placed into the defect through an introducer disc, which pierce both fascial edges simultaneously. An absorbable suture is placed in the delivery needle. The handle is depressed, which releases a metal retrieval loop from the hollow retrieval needle. The suture is passed into the metal loop and the entire device is removed, allowing the suture to traverse the fascial defect for closure (Figure 100.8).

The Puncture closure device (Progressive Medical, St Louis, MO, USA) is a disposable 10-mm instrument with a recessed right-angled needle that can be exposed by rotating a dial at the top of the instrument. The device is introduced through a 12-mm trocar and visualized in the abdomen. The knob is rotated to expose the needle and the device is pulled up out of the port, which causes the needle to draw up through the fascia and subcutaneous tissues. An absorbable suture is loaded through the hole in the needle. The device is then pushed back into the abdomen, rotated 180°, and again brought up through the opposite side of the abdominal wall by removing the instrument from the port. The device is placed back into the abdomen and the needle mechanism is closed, followed by removal of the device (Figure 100.9). The trocar is then removed and the suture is tied approximating the fascia.

Standard technique

In traditional hand-sutured closure, the trocar is removed from the abdominal wall under direct vision while examining the edges of the fascia. The fascial defect is identified and closed in an interrupted or running fashion with an absorbable suture (0-Vicryl or 0-Dexon) on a CT-1 needle. Alternatively, and with

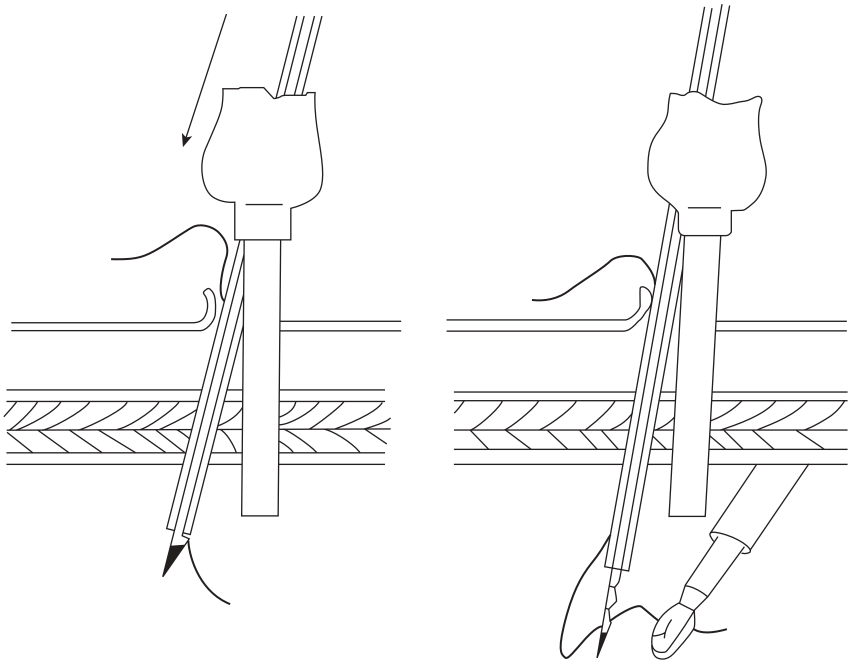

Figure 100.2 Grice needle (Ideas for Medicine Inc, Clearwater, FL, USA) (reproduced from Shaher [14], with permission).

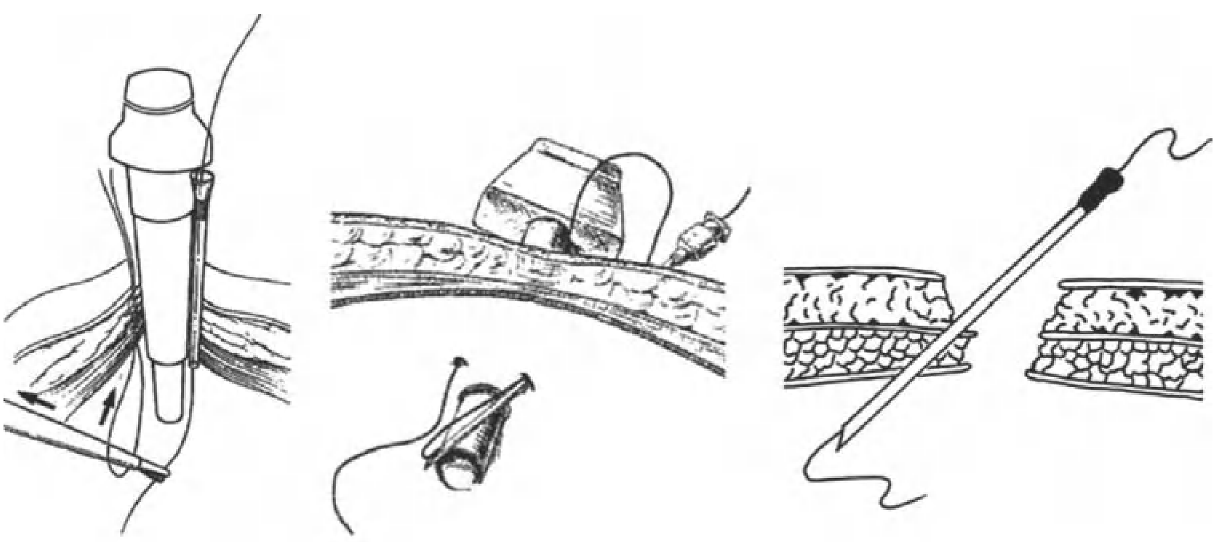

1 2 3

Figure 100.3 Angiocatheter closure (reproduced from Shaher [14], with permission).

smaller extraction sites, a figure-of-eight interrupted suture can be used by first grasping both edges of the fascia with Kocher clamps. A standard suturing technique is appropriate for thin patients where the fascia is easily identifiable. However, in patients with a large amount of subcutaneous tissue, the fascia may be difficult to see and isolate, which can lead to an inadequate closure.

Step 3: Closure of hand-assist devices and organ extraction sites

An organ extraction site or hand-assist port is usually closed prior to the removal of laparoscopic trocars. These incisions are closed in a manner similar to that used for a standard incision in an open surgical procedure. The fascia is closed either in a running fashion or

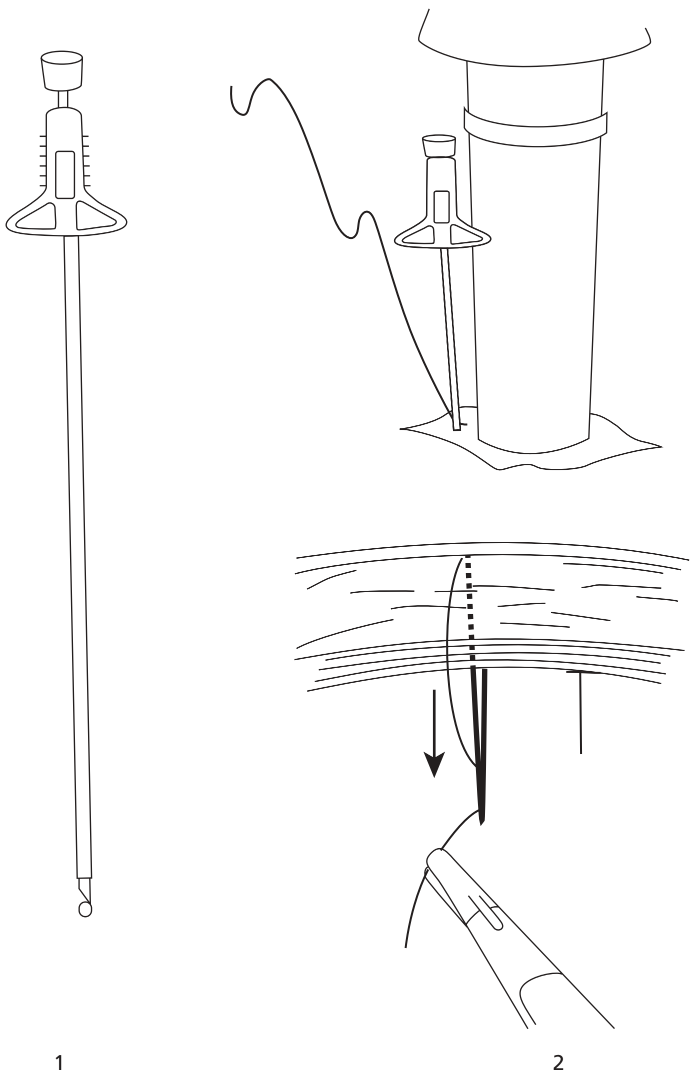

Figure 100.4 EndoClose suture device (Tyco Auto Suture International Inc, Norwalk, CT, USA) (reproduced from Shaher [14], with permission).

Figure 100.5 Carter–Thomason closure device (Inlet Medical Inc, Eden Prairie, MN, USA).

with interrupted figure-of-eight sutures. Following wound closure, the abdomen is reinsufflated to examine the integrity of the closure site and to make sure that abdominal vicera have not been incorporated during the closure. Finally, each trocar is removed under direct vision.

Step 4: Skin closure

Hochberg *et al.* have described the principles of skin closure [17]. Sutures placed in the dermis provide tensile strength to the closure, while sutures in the epidermal layer coapt the skin edges. Edges must always be everted during closure and be tension free. Careful attention to these principles will lead to a cosmetically acceptable result with a high level of patient satisfaction.

Port-site skin wounds may be closed with different techniques, but most commonly with a subcuticular closure with or without the use of transcutaneous skin

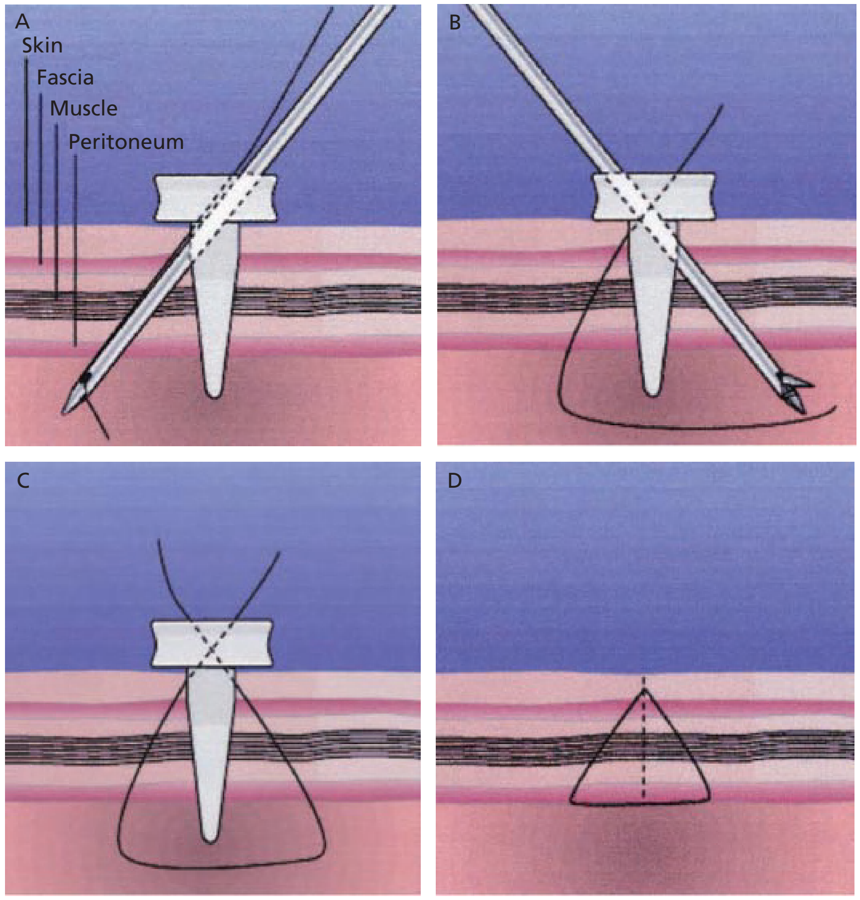

Figure 100.6 (A–D) Carter–Thomason closure.

Figure 100.7 Tahoe ligature device (Tahoe Surgical Instruments Co, San Juan, Puerto Rico).

tape (steri-strips). All port sites should be irrigated thoroughly following removal and prior to closure. Subcuticular closure with a 3-0 or 4-0 absorbable suture will approximate the skin edges adequately. All 12-mm trocar sites must be closed with a subcuticular suture. Smaller port sites (5 mm) are usually closed in the same manner; however, these sites may simply be closed with an adhesive steri-strip that functions to approximate the skin edges. Following skin closure, mastisol liquid adhesive (Ferndale Laboratories Inc, Ferndale, MI, USA) and steri-strips are placed over the incisions for additional re-enforcement.

Skin adhesives

Fast-acting adhesives may be applied to human tissue for wound closure. These adhesives are formed by an association of a monomer and a plasticizer that forms a flexible bond with a breaking strength comparable to that of a 5-0 monofilament suture. The adhesives dry quickly (<1 min) and are used for small incisions such as traumatic skin lacerations and laparoscopic port-site wounds [18]. Dermabond (2-octyl cyanoacrylate; Ethicon Inc, Somerville, NJ, USA) and Indermil (N-butyl cyanoacrylate; Covidien, Mansfield, MA, USA) are examples of commercially available adhesives that are applied following a subcuticular skin closure and do not require the placement of steri-strips or postoperative dressings.

Dermabond has been compared to a running subcuticular closure using a 4-0 Monocryl 25 (Ethicon Inc) in

a prospective randomized trial. Closure with Dermabond was significantly faster than standard closure (155 s vs 286 s, respectively); however, several wound separations were documented in the Dermabond group. There were no wound-related complications with the standard subcuticular closure [19]. A meta-analysis of four randomized studies with 404 patients comparing skin adhesives with suturing for the closure of laparoscopic port-site wounds revealed no difference in wound infection, wound dehiscence, and patient satisfaction [20]. Perry *et al.* reported a severe local allergic reaction to Dermabond after mastectomy [21]. Although these adhesives seem to be a safe and convenient option, additional studies comparing them to standard closure techniques are needed.

Step 5: Postoperative drains

The decision on whether or not to place a surgical drain after laparoscopy is based on the same principles as open surgery. A surgical drain may be indicated in a variety of situations, including fluid accumulation in a large potential space (surgical bed or subcutaneous space), drainage of infected or necrotic tissue, management/prevention of a urinary fistula, and local management of a delayed hemorrhage. Drain placement in most urologic procedures functions to help identify urinary fistulas or "leaks." Procedures such as laparoscopic partial nephrectomy, nephroureterectomy, and radical prostatectomy carry the risk of a postoperative leak that can be identified by either a high volume of output from a drain and/or the presence of an elevated drain fluid creatinine.

Active surgical drains are closed system drains that exert a negative low pressure, which removes fluid gradually. The drains consist of a collapsible reservoir and work by self-suction. Examples include the Jackson–Pratt drain, which is a flexible rubber bulb (100 mL) with a small rubber plug connected to an internal drainage tube (Figure 100.10). Opening the plug and squeezing the air out of the bulb followed by plug replacement creates the self-suction system [14]. A Hemovac or Davol drain is a larger closed-system drain (400 mL), which has a collapsible disc shape with a rubber stopper that works in the same manner as the Jackson–Pratt drain; however, the tubing for Hemovac drains is thicker and less flexible compared with the Jackson–Pratt drain (Figure 100.11). The tubing for active drains may be milked or "stripped," which involves stabilization with one hand of the portion of the tubing that is closest to the patient's body. The other hand pinches the tubing to move blood clots and tissue through the tubing, thus facilitating improved suction.

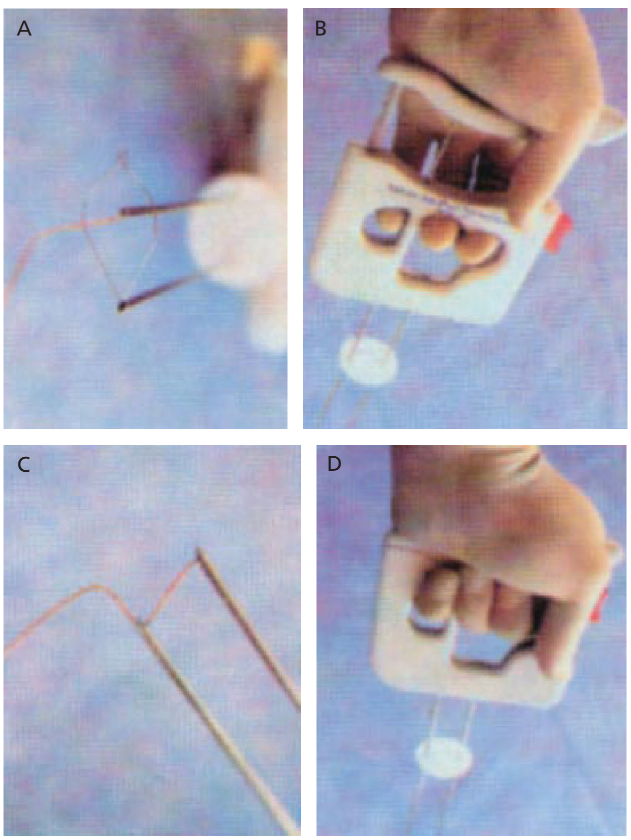

Figure 100.8 (A–D) Tahoe device closure technique.

Figure 100.10 Jackson–Pratt drain.

Figure 100.9 Puncture closure device (Progressive Medical, St Louis, MO, USA).

Figure 100.11 Hemovac drain.

Figure 100.12 Penrose drain (courtesy of Dr. Andrew Bidwell. Veterinarian 121 clinical practice website "wounds and wound care lesson" http://loudoun.nvcc.edu/vetonline/vet121/wound_care.htm accessed June 2011).

Passive drains provide an exit port for fluid, blood, purulent material, and debris, and act via gravity and capillary action. A Penrose drain is a common passive drain that is made of soft latex tubing that is open at either end (Figure 100.12). Penrose drains are often used when the fluid to be removed is too viscous for a closed self-suction drain. Following placement, the drain is sutured into place at the skin level to prevent retrograde migration into the abdominal cavity. A safety pin is commonly used to further prevent migration. The distal end of the drain is covered with drain and dressing sponges to contain the drainage in the postoperative period. Prior study has demonstrated that passive drains are thought to carry a higher risk of infection because they are an open system and allow the migration of bacteria directly into the body. Closed-suction drains are thought to perpetuate a urinary fistula postoperatively and possibly lead to delayed hemorrhage with removal of the drain. Sanchez-Ortiz *et al.* performed a retrospective study on 197 patients undergoing open partial nephrectomy and placement of a retroperitoneal drain to determine differences in postoperative drain-related complications, such as a persistent urinary fistula, delayed hemorrhage, wound infection, and perinephric abscess. Two surgeons placed drains in all cases and the type of drain placed was left to the discretion of each surgeon (37.6% Penrose and 62.4% closed suction). There were no clinical differences between the groups in duration of drainage, tumor size, patient age, BMI, blood loss, or operative time. Although there was variation in the incidence of complications by drain type, none was statistically significant [22].

Common complications with either type of drain include skin infection or inflammation, perinephric wound infections, bleeding, pain, loss of the drain, and retrograde drain migration. Therefore, the risks and benefits of drain placement must be considered after each operation and a drain should be removed as soon as its function is no longer necessary.

Conclusions

Successful laparoscopic surgery depends on a safe and effective method of specimen entrapment and removal, and proper closure of the abdominal wall. A systematic approach to the laparoscopic exit starts with a diligent visual inspection of the operative field and trocar sites for excessive bleeding, organ injury, and organ entrapment. Proper closure of the abdominal fascia and skin can be performed with a variety of hand-suturing techniques as well as laparoscopic closure devices, which allow for direct visualization either during or immediately following the closure. Basic knowledge regarding the use of retroperitoneal drains (indications and complications) is also helpful in achieving a successful result after laparoscopy by limiting the number of postoperative complications.

CHAPTER 101
Complications in Urologic Laparoscopy

David Canes[1], Camilo Giedelman[2] & Rene Sotelo[2]
[1]Institute of Urology, Lahey Clinic Medical Center, Burlington, MA, USA
[2]Robotic and Minimally Invasive Surgery Center, Instituto Médico La Floresta, Caracas, Venezuela

Introduction

While laparoscopy has decreased the morbidity of many urologic procedures, the solutions to complications arising in the minimally invasive environment frequently have no direct open surgical counterpart. For example, laparoscopic access is often obtained through a variety of initially blind punctures where viscera and blood vessels are susceptible to unique injuries. The insufflated abdomen presents specific potential physiologic complications, complex instrumentation can malfunction catastrophically, and inadvertent injury can occur outside the laparoscope's field of view due to unobserved instrument gestures. Laparoscopy therefore requires a specialized knowledge base, and demands a unique set of troubleshooting skills. Whereas textbooks have been devoted to laparoscopic complications, this chapter will cover the main areas pertinent to the urologist in training, as well as for the practicing urologist wishing to broaden their knowledge.

Since urologic laparoscopy is no longer in its infancy and surgical complexity has increased, admonitions about complications from only a decade ago may no longer be appropriate. For example, open conversion is less often required for the contemporary surgeon than it was in the past (early series prior to 2000, conversion as high as 2.1% [1]). While the threshold to convert must remain low, and the window to expeditiously address an evolving complication is short, the options and expertise to intervene without making an incision have expanded. The surgeon must exercise particular care during the learning curve; multiple studies in the urologic [2, 3] and general surgical literature [4] have demonstrated an inverse relationship between surgeon experience and complication rates.

Complications will be organized by major category: (1) access, (2) physiologic, (3) patient positioning, (4) end-organ (vascular, bowel, solid organ), (5) postoperative, and (6) miscellaneous. Where appropriate, complications pertaining to specific urologic procedures will be highlighted. Since robotic techniques have essentially duplicated laparoscopic counterparts for all procedures, all complications discussed herein and their management are generalizable to robotic surgery. The classification schema proposed by Clavien–Dindo will not be specifically reviewed, but the reader is urged to review this separately [5].

Access complications

Regardless of the method to gain initial deliberate entry into the peritoneal (or retroperitoneal) cavity, access remains a significant source of morbidity and potential mortality. The incidence of any type of access injury ranges from 5 in 10 000 to 3 in 1000 [6]. In a recent literature review of 41 articles, including almost 700 000 procedures for which Veress needle access was used, 1575 (0.23%) injuries occurred [7]. The majority (92%) of these injuries were minor. Although the risk of access injury is low, it is not negligible, and a surgeon is statistically likely to encounter several over the course of a career.

The following access techniques are available:

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

• *Veress needle (closed entry)*, whereby a hollow needle with a retractable blunt tip is passed across the abdominal wall. Upon transperitoneal entry, the blunt cannula springs back into place, theoretically blunting the needle tip. Insufflation is then carried out through the needle.
• *Hasson (open entry)*, whereby access is gained via a mini-laparotomy approach and all layers are entered sharply [8].
• *Optical trocar*, a camera-guided approach where the camera sits within the trocar's transparent conical-tipped obturator, and all layers of the abdominal wall can be seen as the trocar is advanced [9]. This technique can be employed alone in a desufflated abdomen or following initial insufflation via a closed (Veress) needle.
• Other techniques, less commonly used in urology, include radially expanding trocars and direct trocar insertion.

A 2008 Cochrane literature review comparing open and closed entry techniques found that there was insufficient evidence to recommend one technique over another [10]. No technique is foolproof. Experts acknowledge, however, that a prospective study powered to detect a meaningful difference would require thousands of patients and is unlikely to be organized. Generalized under-reporting of complications further hampers attempts to define the true incidence of entry complications. However, a careful review of smaller studies reveals some take-home points. The incidence of vascular injury is probably higher with closed techniques [11]. Bowel injury is equally likely with open and closed entry techniques [12], but there may be a higher chance of immediate diagnosis with an open technique, since the injured bowel is directly visualized. Even so, delayed diagnosis of bowel injury has occurred following open access as well [13].

The nuances of safe access are highly subject to individual surgeon preference. As such, evidence-based literature only goes so far, and there is no substitute for hands-on beside training. In our opinion, for instance, Veress needle safety checks, such as aspiration and saline drop, can provide valuable clues when performed correctly and in conjunction with verifying a low opening pressure (ideally < 9 mmHg). A published report on this matter, however, concluded that the ancillary needle checks provided little useful information apart from opening pressure [14]. The literature must be interpreted with caution in this arena, since the most important factor in gaining safe access is surgeon familiarity and mastery of a given approach.

Flexibility to use a different technique when called for is crucial. When the surgeon encounters difficulty gaining access by any approach, the admonition to *change something* is prudent. A quote widely attributed to Einstein captures this concept: "The height of insanity is repeating the same thing over and over and expecting a different result." Stubborn repetition of the same maneuver invites complications. In a difficult access situation, careful reassessment of landmarks, checking for faulty equipment, and evaluating approach angles, can make all the difference. The trocar design must not create false reassurance, as even shielded trocars have not been shown to decrease access injuries. Also, be aware that in obese patients, reliable surface landmarks, such as the association between the umbilicus and aortic bifurcation, are lost.

Table 101.1 Preventive guidelines for laparoscopic access.

- Prior to skin incision, ensure that you have a working camera, insufflation, cautery, and laparoscopic suction
- Choose an entry site at a safe distance from prior scar, as underlying adhesions may be present
- With multiple prior abdominal surgeries, strongly consider open (Hasson) access.
- If a Veress needle is chosen, decide *a priori* on the number of "attempts" you will allow before switching to an open access technique (we recommend three at most). Complications increase as attempts increase [11]
- If you believe that elevating the abdominal wall is important, elevate the fascia (with a traction suture, Kocher clamp, or hand grasping and lifting the abdominal wall); do not elevate the skin only, as this will *increase* the distance to the peritoneal cavity
- Make sure Foley bladder decompression and orogastric tube stomach decompression have been instituted (especially in the pediatric population)
- Ensure anesthesia has achieved complete muscle relaxation. A possible cause of high opening pressure (Veress access) other than preperitoneal needle placement is incomplete patient relaxation
- After the trocar has been placed, look in with the camera immediately. If vascular injury has occurred, the window for diagnosis and intervention is short. Do not waste precious time cleaning the camera lens *prior* to your first look inside

The preventative guidelines in Table 101.1 are not data driven, but rather based on our experience. They are applicable for all types of laparoscopic types of access.

Physiologic complications

Pneumoperitoneum is associated with potential complications and physiologic alterations both from its mechanical compressive effects on blood vessels and viscera, and by its potential entry into the bloodstream and subcutaneous tissues. Carbon dioxide is utilized because it is widely available, noncombustible, colorless, and readily absorbed. An unfortunate by-product of its favorable diffusion properties is the potential to decrease blood pH with prolonged absorption. Patients with severe pulmonary disease in whom the ability to

counteract acidosis with hyperventilation is impaired may have a relative contraindication to laparoscopy [15], but this is rarely encountered clinically.

While other pulmonary changes are best considered expected alterations rather than complications, they warrant mention nevertheless. Metabolic acidosis from hypercapnia can typically be measured in the form of expired CO_2. With mechanical ventilation, the clinical consequences are typically insignificant [16]. The mechanical compressive effects of pneumoperitoneum on the diaphragm causes increased intrathoracic pressure, increased peak airway pressure, and decreased vital capacity.

Hemodynamic effects of pneumoperitoneum are variable and difficult to generalize [16], but a recent prospective study by Meininger *et al*. thoroughly assessed this question by studying 10 patients undergoing robotic prostatectomy using a central venous catheter in place [17]. They were able to accurately measure cardiac output using thermodilution, cardiac index (CI), heart rate, mean arterial pressure (MAP), systemic vascular resistance (SVR), and central venous pressure (CVP), and correlate these with Trendelenburg position as well as pneumoperitoneum. The only hemodynamic parameter associated with Trendelenburg was an increase in CVP. Pneumoperitoneum only resulted in an increased MAP. Importantly, cardiac output was not affected either by Trendelenburg position or by pneumoperitoneum. The reader should note that other studies have demonstrated conflicting results in this arena.

Two important clinical scenarios are frequently encountered. First, the patient is found to have profound bradycardia as an initial response to peritoneal insufflation. The abdomen must be swiftly desufflated and anticholinergics administered. If the physiologic response occurs during a closed (Veress) entry technique, rapid desufflation is not immediately possible, as this can only be carried out after primary trocar placement. In this difficult scenario, the surgeon must proceed rapidly without placing the patient at risk from overly aggressive trocar insertion. Attention to safe trocar placement is well worth a few extra seconds of bradycardia.

Second, if an air embolus is suspected, the often cited Durant maneuver [18] is suggested to prevent the "air lock" from sitting in the right ventricular outflow tract. In the original study, animals that were positioned left side down had improved hemodynamics. In this position with the right side up, and furthermore in Trendelenburg, theoretically the air is prevented from entering the pulmonary outflow tract. A central venous catheter may be inserted to aspirate the air. Some authors have since pointed out that these effects have not been reliably reproduced in the human setting, and the position may be cumbersome and impractical in an emergency situation [19]. Nevertheless, the presentation of air embolus is dramatic, especially if Veress needle high pressure insufflation directly into a major vessel is the cause. The patient develops sudden hypoxia, hypercarbia, and cardiovascular collapse.

The overall incidence of subcutaneous emphysema is 0.4–2.3%[20]. Subcutaneous emphysema is typically clinically insignificant and resolves without specific intervention. It may occur with initial preperitoneal Veress needle insufflation. Alternatively, a combination of a snug skin incision and loose fasciotomy around a trocar allows gradual development of ongoing subcutaneous emphysema during the duration of a case. During lower tract laparoscopy, subcutaneous emphysema in the scrotum and penis is not a subtle finding, and should be manually decompressed at the conclusion of the case.

The presence of subcutaneous emphysema underscores the ability of pressurized gas to diffuse between body compartments [20]. Gas may similarly enter the pleural cavity, mediastinum, and pericardial space. Small collections of air in these spaces, without clinical instability, can typically be managed conservatively since CO_2 is readily absorbed.

Complications of patient positioning

The surgeon often relies on gravity and patient positioning for adequate exposure during minimally invasive genitourinary procedures. Patient positioning, and at times prolonged operative times, predisposes the patient to four potentially painful and debilitating problems if precautions are not taken: neuropraxia/neuropathy, rhabdomyolysis, compartment syndrome, and pressure ulcers [15]. Complications in this arena are position and therefore procedure specific. In a large series of urologic laparoscopic procedures compiled from 15 centers and over 1600 cases, the overall incidence of neuropraxia was 2.7%, including rhabdomyolysis in 0.4% [21]. Risk factors included obesity, longer operative times (>5 h), and advanced patient age. In a postoperative patient with oliguria and myalgias, clinical suspicion of rhabdomyolysis is paramount, creatinine kinase should be checked, and the patient should be alkalinized expeditiously.

For upper tract laparoscopy, with the patient flexed in flank position, the following maneuvers are important: use of axillary roll, avoiding excessive flexion, and padding all pressure points. For lower tract surgery, with the patient supine with arms tucked and legs variably positioned per surgeon preference, hands should be in an anatomic position (thumbs up) and sheets to "tuck" arms must not be overly snug around the arm.

End-organ complications

Vascular injury

Bleeding complications account for a substantial portion of laparoscopic complications. For example,

intraoperative and postoperative hemorrhage accounted for 40% of all perioperative complications in a recent single institution analysis of urologic laparoscopic procedures from 1997–2006 [22]. The overall incidence of vascular injury during urologic laparoscopy is in the range 0.4–1.7% [1, 2].

The most feared vascular injuries carrying the highest chance of mortality when injured are the great vessels and their immediate branches: aorta, vena cava, and iliac vessels. Mesenteric vascular injury can also be a source of major bleeding. The most common scenario is injury by initial blind Veress needle puncture. This may initially manifest as blood aspirated from the needle. Alternatively, vascular puncture from primary trocar insertion can occur. In either case, possible causes include incorrect angle of insertion and/or uncontrolled axial insertion force. In case of injury, if secondary trocars can be swiftly inserted, holding pressure at the bleeding site with a gauze sponge and laparoscopic grasper (unrolled gauze will fit through a 12-mm trocar) usually gives the surgeon time to assess the situation and, if required, proceed with laparotomy in a controlled fashion [23].

Depending on the bleeding severity and origin, the surgeon must decide whether to use thermal energy, clips, or suture ligatures. With massive hemorrhage, immediate laparotomy is often required. One has precious seconds to determine whether initial laparoscopic attempts at control are feasible or futile. A hand-assist port may be placed as an intermediary to open conversion. If open conversion is required, the laparoscope should be lifted up to the abdominal wall and rapid incision made directly over it. In such an emergency, the incision should be generous for maximal exposure. Compression of the bleeding site allows time for anesthesia to catch up with resuscitation, and allows surgeons with appropriate expertise such as vascular surgery to join the team.

The epigastric vessels are the most commonly injured minor blood vessels during trocar or Veress needle insertion [24], when these are placed laterally off midline (Figure 101.1). Using a Carter–Thomason wound closure device [25], sutures placed above and below the bleeding site are usually sufficient to control the bleeding.

A vascular complication specific to retroperitoneal laparoscopic right-sided nephrectomy is inadvertent ligation of the inferior vena cava (IVC) mistaken for the renal vein [26]. The cause is a lack of orientation to anatomic landmarks. During retroperitoneoscopic surgery, the psoas muscle must be maintained as the "surgical horizon" to maintain orientation. The renal vein must be verified to be heading towards the kidney (90° up, if the psoas horizon is maintained), with expected caliber. Most importantly, the renal vein–IVC junction above and below must be confirmed, as a prerequisite to renal vein ligation. If IVC transection is recognized (Figure 101.2), open vascular repair is suggested.

Figure 101.1 Abdominal wall hematoma.

Figure 101.2 Cava transected with vascular stapler, incorrectly identified as a renal vein.

Bleeding is the main complication following partial nephrectomy (1.3–4.3%) [27]. One of the more common causes of intraoperative bleeding is an unclamped, unrecognized accessory renal artery. Great care must be taken both in evaluating preoperative axial imaging and during intraoperative hilar dissection to detect such variations. Delayed bleeding in the setting of hemodynamic stability can be addressed with selective embolization. In cases of hemodynamic instability, re-exploration is warranted. An attempt to ligate bleeding vessels is reasonable, but nephrectomy may be indicated if a single bleeding site is elusive or patient instability does not allow for renorrhaphy. In a large series of laparoscopic partial nephrectomy, reoperation was required in 2% and elective laparoscopic radical nephrectomy was performed in 0.5% [28]. When delayed bleeding manifests as hematuria, vascular fistula should be considered, and can be managed effectively with endovascular embolization.

As with any type of injury, prevention of vascular injury is best A vascular injury "kit" should be prepared with each case (Table 101.2). Dissection should be performed in layers, widely completing more superficial layers before progressing deeper. Vascular injury of varying severity will occur, but poor exposure and "working in a hole" at the outset will severely limit the ability to control an injury. If staplers are used for vascular control, the stapler should be applied a few millimeters distally to provide a stump to grasp in case of catastrophic stapler malfunction [29].

2-0 Vicryl, CT-1 needle, 10 cm long with Lapra-Ty at the end
Titanium clip applier, 5 and 10 mm (available in room, unopened)

Bowel injury

The overall incidence of bowel injury in urologic laparoscopy (Figure 101.3) is approximately 0.2–0.7% [2, 3]. Since initial laparoscopic entry is one of the most common times for complications of any sort, a discussion of bowel complications is intimately related to access (see above). Rather than examining procedure-based datasets, a 2001 review examined international claims arising from access injuries from 1980 to 1999 and revealed that small bowel was the most commonly injured individual organ [13]. In this study, which included 594 injuries in 506 patients, claims were compiled both from legal suits made against a physician, and through mandatory device-related incidents reported to the Food and Drug Administration (FDA). When multiple structures were injured, the most frequent combinations involved both a vascular structure and bowel. Of great practical concern was the observation that diagnosis was delayed greater than 24 h for approximately half of all large and small bowel injuries.

Figure 101.3 Colon injury with primary trocar.

By far the most important take-home message regarding bowel injuries is that the injury may be subtle and early recognition is essential. In the study by Chandler *et al.*, whereas small bowel injury conferred an odds ratio of 1.7 for patient mortality, greater than 24 h delay in diagnosis increased the odds ratio to 3.7 [13]. Even more humbling is that because vascular injuries present so dramatically, delayed bowel injuries are more likely to cause death than major retroperitoneal vessel injury. In another injury-based database based of Medical Device Reports, the mortality rate in cases of delayed bowel injury was 21% [30].

When caused by a Veress needle puncture or trocar tip, laparoscopic repair of large or small bowel with intracorporeal suturing is readily accomplished. For large tears, or when significant adhesions preclude adequate assessment of the full extent of injury, open conversion and repair is recommended.

Figure 101.4 Trocar site hernia.

Trocar site herniation is another potential source of morbidity, occurring in approximately 1% of cases where bladed trocars are used [31] (Figures 101.4 and

101.5). Standard recommendations for port-site fascial closure include all trocar sites in children and trocar sites greater than 10 mm in adults [32]. The latter has been challenged, since newer dilating (nonbladed) trocars leave a much smaller fascial defect than the diameter of the trocar itself [33]. In our opinion, with modern trocar design there is seldom an indication for bladed disposable trocars as their use invites both vascular injury and postoperative herniation.

Rectal injury, one of the most significant injuries during laparoscopic prostatectomy, occurs in approximately 0.5% of cases [34]. During the dissection, all areas of the rectum in relation to the posterior prostate surface are potentially at risk. Rectal injury can happen at the prostate base (incision too posterior through Denonvilliers' fascia, mid gland (wide neurovascular bundle resection), or apex. Preoperative bowel preparation allows for primary closure alone, since lack of gross fecal contamination may obviate the need for concomitant fecal diversion [35, 36]. Intraoperative diagnosis of even small injuries is best performed by instilling air per rectum with the pelvis filled with irrigant, whereby bubbling confirms rectal injury. Digital rectal examination or transrectal balloon placement may reveal larger injuries. Rectal injury may be further complicated by pelvic abscess (0.1%) or rectourinary fistula (0.1–1%) [37].

Predisposing factors for rectal injury include those that impair tissue integrity and/or obscure tissue planes. These include periprostatic fibrosis from multiple biopsies, prior prostate or rectal surgery, previous radiotherapy, locally advanced tumors, prior hormonal therapy, and prostatic infection. A non-nerve-sparing dissection with a wider dissection plane is also a risk factor, and the surgeon must therefore not be complacent in the belief that non-nerve sparing is an easier operative plane.

Rectal injury (Figure 101.6) can be managed laparoscopically or robotically without open conversion [38]. The defect should be closed primarily in at least two layers of nonabsorbable suture. The integrity of closure can be tested by instilling air in the rectum and watching for bubbles in a fluid-filled pelvis. By tacking the rectum laterally to the levator muscles, the rectal closure is drawn away from the urethrovesical anastomosis, minimizing the chance of fistula. A pedicle of omentum can be brought in over the rectal closure. Diverting colostomy or loop ileostomy should be considered in cases of tension at the rectal closure, massive fecal spillage, prior radiotherapy, and delay in diagnosis. A closed suction drain should be placed, and the patient covered with broad-spectrum antibiotics. A cystourethrogram must be performed prior to catheter removal to exclude urine leak, which may progress to rectourethral fistula if not recognized.

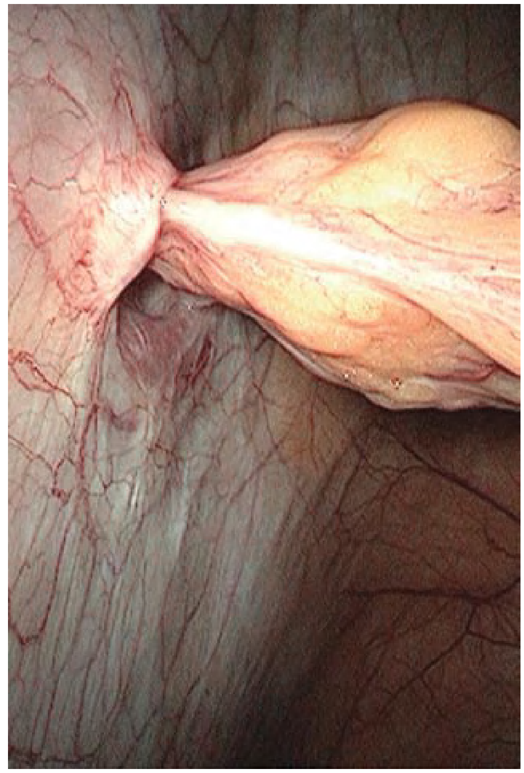

Figure 101.5 Trocar site hernia at time of repair.

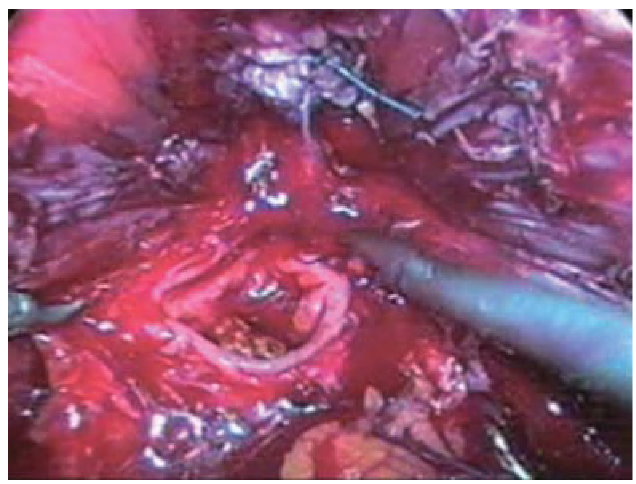

Figure 101.6 Rectal injury during laparoscopic prostatectomy.

Visceral injury

Of solid viscera, the liver and spleen are most at risk during right and left upper tract urologic laparoscopy, respectively. In one of the largest reviews of 2775 urologic laparoscopic procedures, the spleen was injured in 3.2% and the liver in 1.1% of cases [3]. In a meta-analysis broken down by procedure, the spleen was injured in

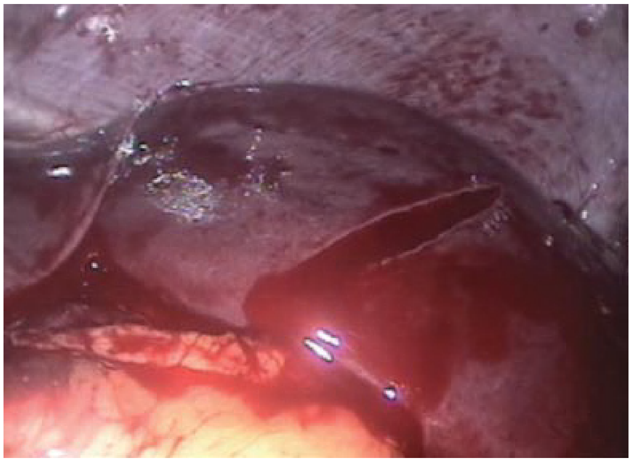

Figure 101.7 Splenic laceration during specimen entrapment.

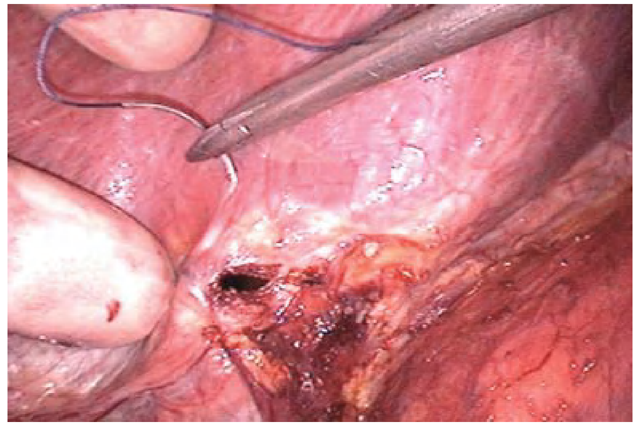

Figure 101.8 Diaphragm injury.

0.5% of radical nephrectomies and 1.3% of donor nephrectomies [39].

Most liver lacerations respond favorably to argon beam coagulation. For both liver and splenic lacerations, hemostatic adjuncts such as Floseal (Baxter, Deerfield, IL, USA) and Surgicel (Ethicon Biosurgery, Somerville, NJ, USA) are also useful. As a last resort, splenectomy should always be considered for severe bleeding or deep lacerations unlikely to resolve with standard maneuvers. The liver and spleen are injured similarly when retracted with an instrument tip rather than a broad surface (Figure 101.7). On the left side, complete mobilization of the spleen from the upper aspect of Gerota's fascia must be accomplished in order to avoid retraction injury.

One commonly encountered scenario is right-sided upper tract (renal or adrenal) surgery in a patient who has previously undergone cholecystectomy and in whom the liver is adherent to the posterior parietal peritoneum over Gerota's fascia. Rather than dissecting the liver directly, the liver should be mobilized with its adherent fascial layers by making an early incision into Gerota's fascia. By entering the retroperitoneum early and reflecting adherent tissue with the liver, injury may be avoided altogether.

The risk of diaphragm injury during urologic laparoscopy was 0.7% in one series [40]. This may occur deliberately as part of planned wide resection of a tumor invading the diaphragm, or inadvertently while dissecting in close proximity to it (Figure 101.8). The first indication that the pleura has been transgressed is a sudden billowing of the diaphragm into the abdominal cavity as the pneumoperitoneum rushes into the chest cavity [41]. Small injuries do not require open conversion to repair. A purse-string suture can be placed laparoscopically around a red rubber catheter exiting through a trocar and immersed in water. As anesthesia expands the lung, the air is evacuated and the suture is rapidly tied down as the catheter is withdrawn [40].

Postoperative complications

Perioperative complications can be classified as either intraoperative or postoperative. In large series, postoperative complications account for approximately half of all complications [1]. The main complications of concern are bleeding (hemorrhage requiring reoperation or transfusion, operative site hematomas), urinoma, and wound complications (infection, hernia). Depending on the procedure, ileus and lymphocele formation are also of concern. The surgeon must be aware that "getting out" safely is as important as gaining access. In this regard, specific maneuvers should be part of standard practice.

Safe laparoscopic exit must include watching all trocar sites for active bleeding after trocar removal. For extirpative procedures requiring an extraction incision, reinsufflating and looking back after fascial closure provides useful information. Lack of bowel entrapment should be confirmed beneath the incision. If significant blood has accumulated during the period of desufflation, an exhaustive search for the bleeding site can obviate the need for re-exploration in the postoperative period. Significant postoperative bleeding presenting with hypotension, anemia, and abdominal distention is a clear sign of hemorrhage, but signs may be more subtle. If a surgical drain has been placed, the rate of filling and quality of fluid are important indicators of bleeding, but absence of blood in the drain does not exclude bleeding. Initial hemoglobin levels may be unchanged before serial measurements uncover anemia.

If surgical exploration is required for postoperative complications, relaparoscopy may be attempted in select cases [42, 43]. If a drain has been placed, it can be used to insufflate the abdomen. Open exploration is fre-

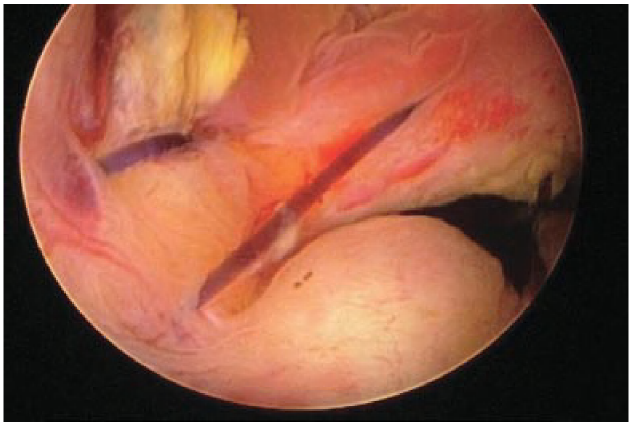

Figure 101.9 Urine leak at urethrovesical anastomosis, anastomotic separation on cystoscopic view.

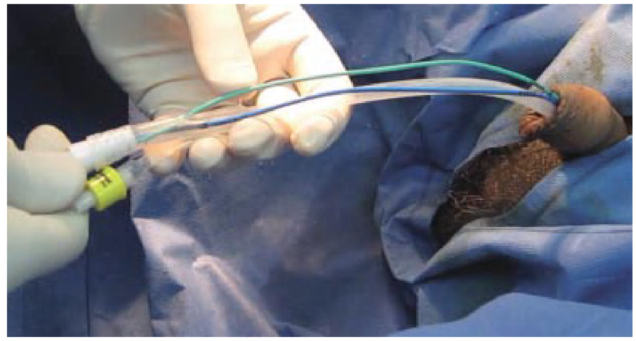

Figure 101.10 Bilateral externalized ureteral catheters alongside Foley catheter for urethrovesical anastomotic leak.

quently required, but generalizations in this regard are difficult. For instance, re-exploration for bleeding following partial nephrectomy in a stable patient may be ideally suited to the laparoscopic approach as exposure of the renorrhaphy bed will be feasible. In contrast, bleeding following cystectomy and neobladder will be difficult laparoscopically as the urinary diversion and mesentery are now space-occupying structures obscuring view, and open exploration is warranted.

Urine leak in the postoperative period is pertinent after laparoscopy, pyeloplasty, and prostatectomy. Management of urine leak after pyeloplasty is initially conservative, as the majority will resolve following a period of encouraging maximal drainage (ureteral stent, Foley catheter, perirenal drain). A persistent vesicourethral anastomotic leak after laparoscopic radical prostatectomy is an uncommon complication with an unclear incidence (Figure 101.9). In one series, the incidence of leak requiring reoperation was 0.9–2.5% [42]. Most urinary leaks occur in the immediate postoperative period and are usually self-limiting with prolonged bladder drainage. Rarely, the surgeon encounters an anastomotic leak that does not resolve in the first 2 weeks.

Several conservative interventions are available for prolonged vesicourethral anastomotic leaks (Figure 101.10). These include prolonged retropubic and bladder drainage, passive rather than active drainage, advancing the drain away from the leak, bladder catheter traction, and bladder catheter needle-vented suction [44]. Particularly when the ureteral orifices are near the anastomosis, invasive techniques should be performed, including placing internalized or externalized ureteral stents. In case of ileus, abdominal pain, and/or urinoma, cystoscopy can provide information as to the degree of anastomotic separation. Laparoscopic re-exploration can be performed, the intra-abdominal urine evacuated, and the anastomosis either redone entirely or additional sutures placed.

Miscellaneous complications

Obturator nerve

The incidence of obturator nerve injury reported for open prostatectomy is 0.1–1%, and for minimally invasive prostatectomy 0.3% [45]. Given that the obturator nerve is fixed at either end, nerve mobilization to gain additional length is not feasible. As such, in the case of nerve loss, an interposition nerve graft may be necessary. If possible, an end-to-end reanastomosis with fine suture is ideal.

To avoid obturator nerve injury, a thorough understanding of normal anatomy is crucial, as this structure is one of the most reproducible, and its position scarcely varies in relation to bony landmarks. During lymphadenectomy, the lymph node packet should first be mobilized distally and reflected completely from the anterior surface of the nerve. When ligating the packet, it should be retracted medially, such that the full nerve is in view. Placing a clip parallel and medial to the course of the nerve will prevent inadvertent nerve injury.

Ureteral injury

Ureteral injury is uncommon during laparoscopic upper tract surgery as its course is familiar to urologists. However, it is occasionally subject to injury during the learning curve of laparoscopic and robotic prostatectomy where its proximity to the seminal vesicle and bladder neck (ureteral orifices) are unexpected and unfamiliar. Ureteral injury was initially reported during the Montsouris posterior approach to the seminal vesical dissection, where the ureter was mistaken for the vas deferens [46]. In general, this is from errant dissection too far laterally. Double checking before ligating or

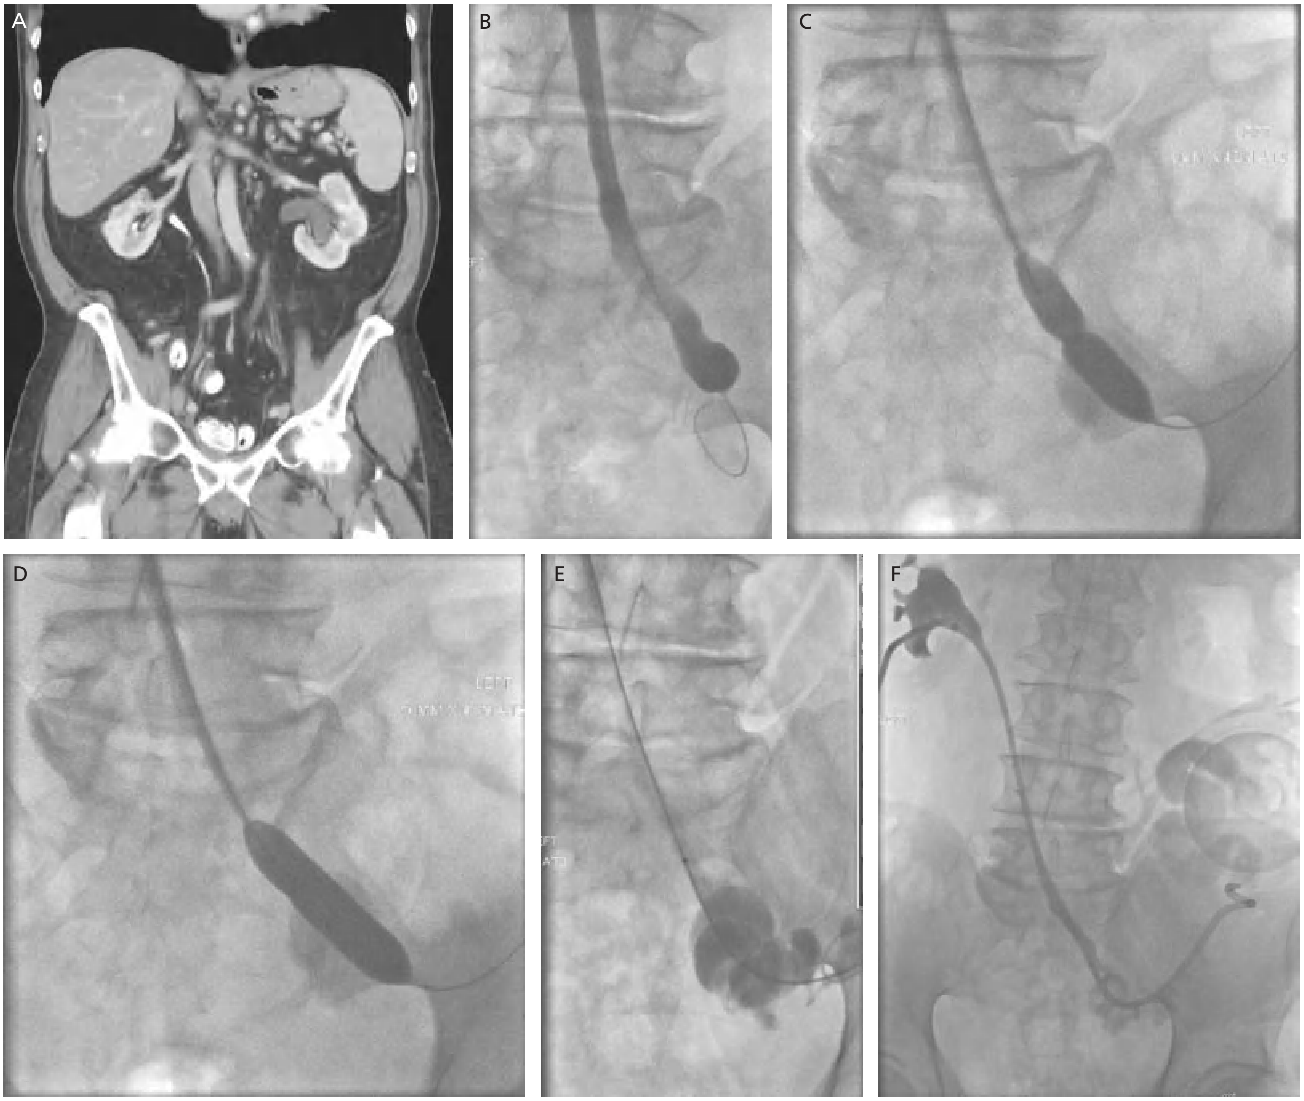

Figure 101.11 Left ureteroenteric anastomotic stricture after robotic cystectomy. (A) Left hydroureteronephrosis on CT scan, (B) cut-off point on antegrade nephrostogram, (C, D) balloon dilation, (E) contrast flow into ileal loop, (F) nephroureteral stent in place.

dividing a tubular structure will prevent ureteral injury in this context. The other area of potential ureteral injury is the trigone. Care must be taken both during the posterior bladder neck dissection and during the anastomosis to identify the ureteral orifice. The incidence of ureteral injury during laparoscopic prostatectomy is approximately 0.8% [36, 47].

When ureteral injury is diagnosed intraoperatively, management depends on the injury type. Focal contusion without thermal energy may be managed conservatively with a ureteral stent alone. Suture repair and stenting of partial lacerations are appropriate. For complete transection, end-to-end anastomosis may be possible, but reimplantation is often a safer solution. When detection is delayed, repair is dictated by the location and extent of the injury, with the majority of injuries below the iliac vessels being managed with reimplantation. Percutaneous antegrade balloon dilatation may be suitable for delayed ureteric anastomotic stricture (Figure 101.11).

Conclusions

Comprehensive preoperative planning and surgeon preparation can minimize or prevent complications from minimally invasive surgery. Particular care must be exercised during the learning curve, as multiple series have demonstrated that complications decrease with experience. The impact and sequelae of complications when they do occur can be minimized by rapid recognition and appropriate treatment. Humility is important; the first step in recognizing complications

is being open to their occurrence. With this broad overview, the reader should be better placed to avoid complications, equipped to swiftly diagnose them, and more able to intervene should they occur.

CHAPTER 102
LESS and NOTES: History and Introduction

Pradeep P. Rao & Prashanth P. Rao
Mamata Hospital, MIDC, Dombivli, Mumbai, India

Introduction

Surgeons have traditionally used large incisions on the abdominal wall to access the organs within, believing in "big cut, big surgeon." While this may have been true in the days of poor illumination and instrumentation, rapid improvements in these has meant that safer surgery can be done with less exposure. Cosmetic appearances became important to the patient once the basic safety of surgeries was established. This culminated in the development of laparoscopic surgery, where an endoscope and instruments passed through multiple small incisions are used to operate on organs within the abdominal cavity. Laparoscopy has progressed to a point where it is accepted as a gold standard for many commonly performed abdominal surgeries.

Urologists have been at the forefront of minimally invasive surgery from the beginning. They have been the pioneers in using natural orifices to operate on genitourinary organs. Transurethral resection of the prostate (TURP) remains the gold standard in the operative treatment of benign prostatic hyperplasia (BPH). The pioneering efforts of Clayman and Gaur heralded the entry of urologists into laparoscopy and retroperitoneoscopy [1, 2]. It is now over 20 years since Clayman performed the first laparoscopic nephrectomy, and laparoscopy is now routinely performed for many benign and malignant conditions of the genitourinary tract. It is now common to perform even complex reconstructive surgeries in a minimally invasive fashion. The trend towards minimally invasive surgery has progressed to a point where it is possible to operate on the patient without any external incision or by hiding the incision so that no scar may be visible.

Natural orifice translumenal endoscopic surgery

The first description of the procedure known as NOTES (natural orifice translumenal endoscopic surgery) is credited to Kalloo *et al*. in 2000, and published in 2004; they demonstrated the feasibility and safety of a per oral transgastric endoscopic approach to the peritoneal cavity with long-term survival in a porcine model [3]. Meanwhile, Gettman *et al*. in 2002 published the first description of a natural orifice surgery in a series of transvaginal porcine nephrectomies [4]. Rao *et al*. reported the first human case of NOTES in 2004 with a transgastric appendectomy [5]. It was becoming clear that this was an emerging field of minimally invasive surgery, and regulation of procedures performed and guidance to physicians intending to perform these procedures was vital to the growth of these surgeries.

In July 2005, some of the leaders in this field who represented the American Society of Gastrointestinal Endoscopy (ASGE) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) met, and their deliberations were published as a White Paper of the ASGE/SAGES working group on NOTES [6]. The paper discussed the possible technical barriers to NOTES; recommended the involvement of a surgeon and endoscopist in any team carrying out these

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

procedures, and sharing of complications with other groups doing similar procedures via a central registry; and emphasized the need for Institutional Review Board (IRB) approval before using this approach in humans. The working group was named the Natural Orifice Surgery Consortium for Assessment and Research (NOSCAR). NOSCAR has met four times since this initial meeting. It continues to set the standards for the development of the specialty, documents new techniques, and maintains a database of the procedures that have been done.

Pure NOTES

"Pure" NOTES describes the procedure performed through natural orifices only: trangastric or transesophageal (through the oral cavity), transvaginal, transcolonic or transvesical. All these routes have been reported in animal models. Most human cases of pure NOTES have been transgastric or transvaginal.

The transgastric route is the commonest route described for NOTES procedures so far. Gastrointestinal endoscopists are the most familiar with this route and they have driven the innovation in this field. The primary difficulties associated with this route appear to be the lack of a device for secure closure of the stomach [7], difficult orientation after retroflexing the scope in the peritoneal cavity, particularly for a cholecystectomy or upper abdominal procedures, as well as inadequate illumination of the capacious peritoneal cavity.

The transesophageal route also has been used to access the mediastinum in an animal model and various procedures can be performed, including pleural biopsy and cardiomyotomy [8].

The transvaginal route has been used for NOTES with some success. It is the most commonly used route in urologic applications with a fair number of reports of procedures performed in animals by this route [4, 9]. This route was also used in the first human urologic experiences of pure NOTES, as well as hybrid techniques, for performing nephrectomies [10, 11]. Closure of the vagina is fairly easy and being a capacious organ, it is possible to use rigid laparoscopic instruments which surgeons are more familiar with. Using this route obviously excludes the male population. Some gynecologists remain concerned about adhesions in the pelvis and subsequent infertility after these procedures. There are also concerns about spread of endometriosis and that this also may lead to dyspareunia in the postoperative period [12].

Unlike the transvaginal route, the transcolonic route is not gender specific. A NOTES sigmoid colectomy with primary anastomosis has been reported using this route in a human cadaver model [13]. The main problems with this route are contamination of the peritoneal cavity with colonic contents and unreliable closure of the colon after the procedure.

The transvesical route is attractive to urologists who are familiar with the organ. The bladder can be closed with endoscopic suturing techniques and a small rent can also heal with just catheterization. Only experimental surgeries have been performed by this route so far [14].

Multiportal NOTES

Rendezvous NOTES is an approach where more than one portal of entry is used to avail of triangulation or better vision or safety in doing the procedure. In these techniques, which remain experimental, transgastric/transcolonic routes have been used for cadaveric small bowel resection, and the transgastric/transvaginal approach has been used for porcine nephrectomies [15–17].

Hybrid NOTES is the use of any natural orifice together with one or more transabdominal laparoscopic ports. The lack of effective clipping/stapling devices for use through flexible endoscopes make it much easier to carry out these tasks through the additional laparoscopic port. Also, use of an additional transumbilical access, albeit a needlescopic port for visualization of entry into the peritoneal cavity via the viscus, makes the procedure much safer. As will be seen during the discussion on LESS below, the cosmetic sequelae of a port in the umbilicus are negligible. This has been the commonest type of procedure done in humans [18, 19] and has been used for a variety of procedures, including radical nephrectomy and cholecystectomy [11, 20].

Hybrid NOTES should be seen as a stepping stone in developing the technique of pure NOTES. It helps the surgeons to gain experience in the use of and the view with flexible endoscopes, while ensuring safety for the patient undergoing these new procedures.

Robotic NOTES is an exciting new development. There have been reports of using the da Vinci surgical robot (Intuitive Surgical, Sunnyvale, CA, USA) in animals to perform various reconstructive and ablative urologic procedures [21, 22] Most of these reports use hybrid NOTES as the cumbersome nature of current robotic systems mean that otherwise the arms would clash. The most interesting development in this area is the use of flexible robotics and mini-robots to carry out different procedures. Flexible robotics has been used clinically with success to perform renoscopy to fragment renal calculi [23–25]. The NOSCAR working group in 2008 identified access, navigation, maneuverability, and stability to withstand instrument forces as the essential requirements for a successful NOTES platform. There is no single NOTES platform that can deliver all of these. Robotics might have the answer. A multichannel flexible

robotic device has been used in a cadaver study by the transgastric route [26]. *In vivo* mini-robots have been described experimentally that can be introduced into the peritoneal cavity via a natural orifice to explore the peritoneum and perform surgeries [27, 28].

Difficulties

There are various problems associated with NOTES. The perforation of a "normal" viscus to get at an abnormal organ seems to contravene the natural process of commonsense, besides being hazardous, should the closure be insecure, or leak post procedure. Regarding the transvaginal route, this excludes half the population, may not be appropriate in the younger population who have not completed child bearing, and may even be difficult and unethical in sexually inactive young patients.

The instruments being used for NOTES today are the standard off–the-shelf double-channel endoscopes and also sometimes rigid laparoscopic instruments for hybrid NOTES. The passage of two instruments down the channel of the endoscope considerably limits their use [5]. It is difficult to hold and retract normal organs with the flimsy endoscopic instruments, let alone organs inflamed and enlarged by disease. Use of a flexible endoscope to pass these instruments has the disadvantage of excessive mobility, making these procedures more cumbersome as the endoscope easily gets lost in the insufflated and capacious abdominal cavity. Also, it is difficult to achieve triangulation as the channels are parallel.

NOTES is an exciting new technology but has a long way to go before it can be used routinely in clinical practice. Development of newer materials and instruments will likely improve the practice of these types of surgeries. Overcoming the remaining obstacles will require close cooperation between engineers and surgeons. Variations like hybrid NOTES and newer technologies like LESS surgery are stepping stones towards the fully fledged utilization of NOTES in clinical practice.

Laparoendoscopic single-site surgery

The development of new multichannel access devices and articulating instruments has lead to another exciting new advance in laparoscopic surgery; laparoendoscopic single-site surgery (LESS) [29]. The first cases of single-port access in urology were reported by Rane and Rao using a new access device, the R-Port™ (Advanced Surgical Concepts, Wicklow, Ireland). The cases, which included the first successful single-port nephrectomy and ureterolithotomy, were performed in May 2007 [30, 31]. At around the same time, Cadeddu *et al*. were working on a similar technique, using three separate trocars through a single incision in the umbilicus to do nephrectomies. They reported this procedure in an animal model as well as in the first human clinical cases [32]. Desai *et al*. used the R-Port for reconstructive as well as ablative procedures through the umbilicus in clinical cases, giving almost a scarless appearance post surgery [33]. The umbilicus is a ubiquitous cicatrix from birth and can be used to conceal the access into the abdominal cavity.

Single-port laparoscopy is not new. It has been around for more than 30 years. Gynecologists have been performing tubal ligation with a single puncture laparoscope since it was introduced in the late 1970s [34, 35]. This technique, however, is only applicable to the most basic surgery, especially gynecologic surgery where the uterus can be manipulated from below, obviating the need for retraction. These early instruments had offset eyepieces with a straight operating channel through which an instrument (usually an applicator for the ring to occlude the tubes) could be passed [36, 37]. The advantages of using a second instrument with triangulation were noted at the time [38]. The use of multiple trocars rapidly gained popularity because of the disadvantages of using a single puncture.

As conventional laparoscopy became popular even for complex reconstructive procedures in surgery and urology, it was usually carried out through –three to six ports. However, the increasing numbers of ports led to reduced cosmesis, more pain, and increased risk of complications due to port-site infections and hernias [39, 40], and reducing these complications was an incentive to develop techniques that employed fewer ports. While NOTES represents the ultimate in minimally invasive surgery by avoiding abdominal incisions altogether, single-port/single-site surgery is a step towards that goal [41]. Also, while there were isolated reports of purely transumbilical surgery, the lack of adequate access devices and instrumentation prevented the spread of the technique at the time [42].

Terminology

As more and more centers started doing this type of surgery, papers were published using different nomenclatures for the surgery [31, 32, 43–48] (Table 102.1). There was a need to unify the nomenclature under a single umbrella similar to NOTES so that it would be easier to document new developments and guide this emerging technique of minimally invasive surgery. A multidisciplinary consortium of surgeons, named LESSCAR (Laparo-Endoscopic Single Site Surgery Consortium for Assessment and Research), was brought together by Gill at Cleveland in July 2008. It suggested the term LESS for all procedures using a single site or single port for access. The consortium also suggested a standardization for reporting these surgeries, "To clearly

Table 102.1 Acronyms used to describe single-port/single-site surgery.

SPA: single port access
SILS: single incision laparoscopic surgery
OPUS: one port umbilical surgery
E-NOTES: embryonic natural orifice transluminal endoscopic surgery (as the umbilicus is an embryonic structure)
SIMPLE: single incision multiport laparoendoscopic surgery
SPS: single port surgery
VSUS: visibly scarless urologic surgery
SIL: single incision laparoscopy
SPL: single port laparoscopy
R-NOTES: robot-assisted natural orifice transumbilical endoscopic surgery
U-NOTES: umbilical natural orifice transluminal endoscopic surgery
LESS: laparoendoscopic single-site surgery
NOTUS: natural orifice transumbilical surgery
TUES: transumbilical endoscopic surgery
TULA: transumbilical laparoscopic surgery
SLaPP: single laparoscopic port procedure

and fully convey all procedural details, a 'mandatory descriptive second line' should be required in all scientific publications, which succinctly provides all relevant information at the very outset, such as: single incision length and location [abdominal (umbilical or extra-umbilical), thoracic, or pelvic]; approach (transperitoneal, retroperitoneal, percutaneous intraluminal, transluminal); number/type of ports used; laparoscopic, endoscopic or robotic; type of laparoscope used (straight or flexible); type of instruments used (straight, curved, bent, articulating, or flexible); and whether any ancillary 2-mm needlescopic instrumentation is employed" [29]. Similar to NOSCAR, the mandate for LESSCAR included creating a multidisciplinary group, soliciting funding, establishing a registry and database of procedures performed, coordinating LESS research, and collaborating with other established professional organizations to facilitate LESS presentations at their meetings. The criteria for LESSCAR membership were kept inclusive so as to allow maximum participation, while insisting on IRB approval to carry out LESS clinical research [29].

Development of LESS

The main problems with performing LESS surgery are a loss of triangulation, clashing of instruments and the endoscope which are close together, and a lack of maneuverability. This new technique of surgery could progress only by circumventing these issues. LESS has mainly been driven by the availability of new technologies, which have enabled surgeons to overcome these difficulties.

Table 102.2 Solutions to problems in single-site surgery.

Problem	Solution
Damage to light fiber of conventional laparoscope	Use of optic with coaxial light fiber (e.g. EndoEye™)
Clashing of telescope with instruments	Use of deflectable tip telescope
Loss of triangulation	Use of articulating or prebent instruments
Clashing of trocars within the abdominal cavity	Use of short trocars
Multiple sheath incisions leaving Swiss cheese defects	Use of access device with single incision (Triport, Quadport, SILS port, XCone)

The early experience with LESS can be attributed to the development of new access devices (the R-Port™ and the Uni-X™) and new articulating instruments (Real Hand™ (Novare Surgical Systems, Cupertino, CA, USA). These new access devices permit the surgeon to insert more than one instrument (and an optic) through the same port [30, 31, 49, 50]. The articulating instruments can be used through conventional straight trocars, which were passed through a single site (usually the umbilicus) to give a sense of triangulation (see below) [32, 47]. When short trocars are used in this technique, they reduce (but do not completely prevent) the clashing of the instruments close to the abdominal wall.

As with most new surgical techniques, the early development of LESS surgery was mainly about overcoming the various problems associated with a new approach. Each problem had to be identified and a solution sought (Table 102.2). Fortunately, technology in optics and instrumentation has just about reached the point where this is possible. A few novel ideas like prebent instruments were developed with this type of surgery. Prebent Instruments cannot be passed through conventional trocars which are straight and rigid [30], but they can be passed through some of the newer generation access devices like the Triport and Quadport, which have a very low profile inside the abdominal wall. Articulating instruments were originally developed to mimic the freedom of movement afforded by the robotic wrist of the da Vinci surgical robot and were to be used through the conventional straight trocars used by the robotic arms. They were ideally suited to be used by the first surgeons doing single-site surgery through the umbilicus using conventional straight trocars, giving a sense of triangulation. Triangulation is

one of the fundamental concepts of laparoscopic surgery, as it permits traction on tissues to facilitate dissection along normal anatomic planes. Articulating instrumentation allows for triangulation to occur intracorporeally despite the trocars being adjacent to one another through the same skin incision [32]. Instruments may cross at times. Also, as initially demonstrated by Raman *et al*., the use of a deflectable tip laparoscope is uniquely suited to this type of surgery [47]. It must, however, be noted that use of this type of laparoscope does have a learning curve for the assistant holding the scope.

In addition to the use of the new devices, single-site surgery was also carried out using access devices that were already available, along with regular laparoscopic hand instruments [51]. Some of the earlier hand-access devices like the Gelport are suited to single-incision surgery as they allow multiple instruments to be passed through them. They have the additional benefit of allowing the specimen to be removed easily after ablative surgeries.

LESS and NOTES:the present and future

Since the introduction of single-site surgery in 2007, it has rapidly gained popularity with surgeons as well as manufacturers. Several hundred cases have been performed with a significant number being reported in peer-reviewed journals [52, 53]. Much new equipment has been developed for this in a very short period of time. This is in stark comparison to NOTES for which clinical data have only recently been published in spite of the availability of the procedure for about 10 years. The reasons for this are obvious.

With LESS, the surgeon has a more conventional view of the field of surgery as compared with a transvaginal or transgastric view. The equipment used for LESS is familiar to urologists already doing laparoscopic surgery. Most importantly, it is easy to convert LESS to conventional laparoscopy by adding a few trocars. This ensures the safety of the patient during the surgeon's early experience [54]. Most of the reported LESS procedures seem to have equivalent efficacy to conventional laparoscopy, including operative times, blood loss, and length of hospital stay. What remains to be seen with time and increasing numbers of cases, which will lend statistical validity to the comparisons, is whether LESS offers enough advantages (cosmetic or otherwise) to coexist with conventional laparoscopy. There is a significantly longer learning curve with LESS than for conventional laparoscopy and the benefits need to outweigh the increased difficulties of learning and performing these techniques. Comparisons are already being made in surgeries such as donor nephrectomies [55, 56]. This is where LESS can make a significant contribution by expanding the donor pool. It needs to be determined if this is a meaningful and lasting technique or a stepping stone towards a truly scarless intervention [57].

With NOTES, surgeons are not used to the endoscopic views and in urology, it remains a research interest, although a few experienced surgeons have performed the occasional clinical case [10, 11]. Although undoubtedly a very attractive concept, for NOTES to be used routinely in urology, instrumentation and optics need to improve to the point where a good outcome can be assured. NOTES is one of the most exciting new clinical modalities and considerable advances are bound to be seen over the next few years in this field.

CHAPTER 103

NOTES: Instruments, Platforms, and Endoscopes

Mark D. Sawyer & Lee E. Ponsky

Center for Urologic Oncology & Minimally Invasive Therapies, Urology Institute, University Hospitals Case Medical Center, Cleveland, OH, USA

Introduction

Natural orifice extraction of internal organs without disfiguring cutaneous incisions can be dated back approximately 2500 years with the embalming process of cadavers by the ancient Egyptians in which the brain was removed transnasally, a process described by the Ancient Greek author Herodotus [1]. It was not until the early 20th century that transnasal transphenoidal surgery was used for therapeutic procedures [2]. The initial transrectal procedures and first documented endoscopic procedures were use of the transrectal speculum using natural light in the fifth century BC by the Kos school of Hippocrates. A variety of other endoscopic specula were used in the ancient and medieval periods for the vagina, nares, and ear, using natural light [3]. According to a review by Baskett, the earliest use of a natural orifice for extirpation of internal organs in living humans was likely by the ancient Greeks [4]. Themison of Athens is credited with removal of the prolapsed uterus in women who subsequently survived the procedure in the first century BC. The first documented description in modern times was by Berengario da Carpi who performed the vaginal removal of a prolapsed uterus in 1517. Sauter of Baden reported the first planned vaginal hysterectomy for cervical cancer and gave the first clear description of entry into the abdominal cavity, demonstrated by prolapse of bowels through the incision in 1822. This patient survived for 6 months [4]. This latter case demonstrates the initial report of peritoneal access through a natural orifice incision occurred nearly two centuries ago, albeit as a complication.

Other natural orifices were also used earlier in the modern era for access to internal organs in living patients. Bezzini described the first cystoscope in 1805 but was apparently unable to use it clinically due to poor visualization and the heat of the instrument [3]. With subsequent developments, therapeutic procedures of the bladder became possible later in the 19th century. The ureter and renal pelvis were first accessed transurethrally by Hugh Hampton Young in 1912 [5]. Although there were descriptions of rigid rod scopes being used in the 1870s, effective gastrointestinal endoscopy, whether to access the stomach and duodenum perorally or to visualize the entire colon with colonoscopy, depended on the development of fiberoptic flexible endoscopes, the first of which was successfully used in 1957 [3].

The development of laparoscopy represented a means of performing intra-abdominal procedures with small transcutaneous incisions and use of scopes rather than the relatively large incisions that were traditionally required. Laparoscopy, as a concept, was first introduced by Kelling in the early 1900s with insertion of a rigid Nitze–Leiter cystoscope into the canine abdomen to perform peritoneoscopy [6] However, laparoscopy was limited mostly to gynecologic surgeons who used the modality typically for diagnostic peritoneoscopy and simple procedures such as elective sterilizations.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Acceptance of laparoscopy for more complicated therapeutic procedures did not occur until the 1980s with the adaptation of laparoscopy for cholecystectomy coupled with improvements in video capabilities [3]. In urology, the new modality was used to perform a laparoscopic nephrectomy in 1991 by Clayman *et al*. [7] and was subsequently adapted to a wide variety of urologic procedures.

Intentional use of natural orifices as an access point for abdominal, retroperitoneal, pelvic, and even thoracic laparoendoscopic surgery is a new phenomenon. Gettman *et al*. described the initial laboratory work with transvaginal nephrectomy in the porcine model in 2002 [8]. However, an explosion of interest in natural orifice surgery followed from the work of Kalloo's group who described a variety of transgastric surgical procedures in the porcine model [9] and a video by Reddy and Rao of a completely transgastric appendectomy in the clinical setting [10], both in 2004. Natural orifice translumenal endoscopic surgery (NOTES), as these approaches have been collectively termed, thus represents a convergence of laparoscopy and endoscopy to perform surgery that would traditionally have required access by cutaneous incisions using endoscopic equipment that is introduced through natural orifices. As such, it is a promising development in minimally invasive surgery, which could represent a new paradigm in surgical management.

The term NOTES was adopted by a consortium of gastroenterologists and general surgeons called NOSCAR (Natural Orifice Surgery Coalition for Assessment and Research) in 2005 [11] and has gained acceptance in other specialties including urology [12]. While an obvious advantage of NOTES over other surgical procedures is improved cosmesis, practical benefits of NOTES could include potential for reduced postoperative pain, anesthesia requirements, and adhesions, and risk of infections and incisional hernias, as well as possible advantages in morbidly obese individuals [13, 14]. A number of challenges remain, including safe access and closure, especially in orifices with a high bacterial load.

The concept of NOTES clearly stimulated an interest in "scarless surgery," while also challenging the traditional paradigm of triangulation of instruments. Coupled with the recognition of limitations of existing equipment and platforms and other concerns of natural orifice surgery, much of this enthusiasm was then channeled into the development of laparoendoscopic single-site surgery (LESS). The latter is now becoming increasingly popular for clinical applications and can be virtually scarless when performed at the umbilicus. Alternatively, two intermediate approaches that straddle the two concepts are "hybrid NOTES" and "hybrid LESS," which involve a combination of natural orifice and transcutaneous approaches. The distinction between these terms primarily reflects the degree to which the natural orifice is used to perform the procedure, although a hybrid NOTES procedure can involve more than one cutaneous incision, while a hybrid LESS procedure involves only a single incision [12]. Indeed, with exceptions, most of the clinically described NOTES procedures to date have involved hybrid procedures.

This chapter will describe current applications of NOTES both clinically and in the laboratory, and will review some of the major challenges of translumenal approaches. Conventional and novel equipment and platforms that have been used to overcome these obstacles will then be discussed. Due to rapid innovation in the field, we would caution that any attempt to exhaustively detail the equipment used in these new approaches will rapidly become obsolete. Therefore, general concepts are emphasized with the described equipment being illustrative of approaches that have been used to date by various researchers and not necessarily an indication of commercial or practical feasibility in the clinical setting.

Overview of natural orifices and NOTES procedures

The natural orifices that could theoretically be used to access the abdomen and retroperitoneum include the vagina, oral cavity, nares, urethra, and rectum. However, the terminology used to describe the NOTES procedure emphasizes the organ that is incised, as the orifice used is typically implied. For example, the vast majority (if not all) transgastric procedures to date access the stomach transorally rather than through the nares. The NOTES procedures described below are categorized by NOTES access.

Vagina (transvaginal)

As already described, a vaginal approach has long been used for extirpative surgery with documented peritoneal access almost two centuries ago. Given the ease of access, this orifice is perhaps the most promising for insertion of endoscopic or even laparoscopic cameras and instrumentation. As noted, the initial translumenal endoscopic procedure was the pure NOTES nephrectomy in the porcine model by Gettman *et al*. in 2002 in a study that predated the term NOTES (8). In actual clinical practice, the vagina has been the most utilized NOTES access to date for abdominal and pelvic procedures. The first transvaginal NOTES procedures in humans were likely the transvaginal NOTES cholecystectomy reported by Zorron *et al*. in 2007 [15] and the transvaginal NOTES appendectomy reported in 2008 by Palanivelu *et al*. [16].

The first clinical procedure in urology that qualifies as NOTES in the purest sense was the transvaginal radical nephrectomy performed in 2009 by Kaouk *et al*. [17]. They reported that all operative steps were performed transvaginally, including removal of the intact kidney transvaginally without assistance of additional ports. For this procedure, they used a vaginally placed GelPort™ device (Applied Medical, Rancho Santa Margarita, CA, USA). Leading up to this important accomplishment were several reports of hybrid transvaginal NOTES nephrectomies. In 2007, Branco *et al*. described a hybrid nephrectomy with two 5-mm abdominal trocars and the scope through the vagina [18]. Sotelo *et al*. then reported in 2008 a hybrid transvaginal NOTES nephrectomy using only an umbilical access transabdominally, consistent with the goal of scarless surgery [19]. A hybrid transvaginal donor nephrectomy was also described in the press by Allaf *et al*., also in 2009, but has not been formally published as of this writing, and involved three abdominal incisions one of which was at the umbilicus [20]. Transvaginal NOTES retroperitoneal nephrectomy has also been described in the porcine model [21]. Clearly a major limitation of this approach is its applicability to only half the population as it is limited to women.

Oral cavity/stomach (transgastric)

As noted above, Kalloo *et al*. described the initial intentional use of the stomach to access the peritoneum and perform surgeries in the porcine model [9], which was followed soon thereafter by Reddy and Rao's therapeutic transgastric NOTES appendectomy video shown at a conference in 2004 (although the work remains unpublished) [10]. Marks *et al*. described a bedside transgastric PEG "rescue" in an intensive care patient with a dislodged gastrotomy tube in 2007 [14] A prospective clinical study of transgastric diagnostic peritoneoscopy in ten patients was reported to have favorable results [22]. There have now been a wide variety of transgastric procedures performed to date in the laboratory. There is also a growing experience with urologic NOTES procedures using transgastric access. Transgastric NOTES renal surgery in the porcine model includes combined transgastric and transvaginal nephrectomy by our group [13] (Figures 103.1 and 103.2); combined transgastric and transvesical nephrectomy by Lima *et al*. [23]; and transgastric partial nephrectomy by Boylu *et al*. [24]. Our group also evaluated the bladder by performing transgastric NOTES partial cystectomy [25]. Despite significant interest in this approach, there remain significant questions of safe access and closure, especially given difficulties in sterilizing the stomach and potential for gastric leakage.

Figure 103.1 Balloon dilation of colpotomy. View from a transgastric pediatric endoscope.

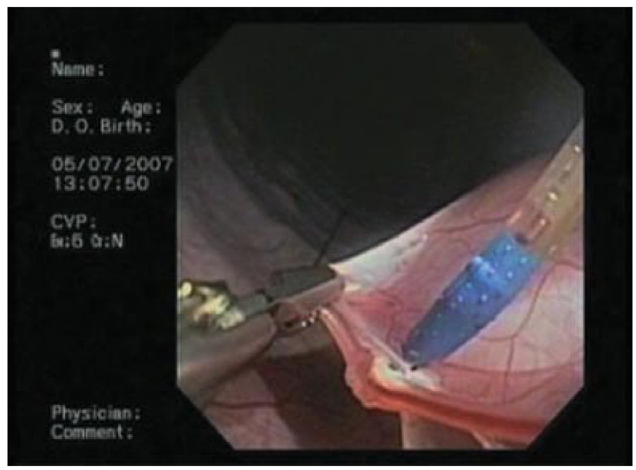

Figure 103.2 Dissection of perirenal tissue using a needle knife device through the gastroscope in combined transgastric and transvaginal NOTES nephrectomy.

Urethra/bladder (transurethral/transvesical)

A significant advantage of a transvesical access is the relative sterility of urine [26], but the relatively small size of the orifice has limited investigations. To date there has been to our knowledge only a single clinical report of intended transvesical peritoneoscopy. This report used a flexible ureteroscope through a vesicotomy that was first balloon dilated [26]. In a human cadaveric model, Humphreys *et al*. described a transurethral NOTES radical prostatectomy [27]. In the porcine model, Lima *et al*. used transvesical NOTES approaches for peritoneoscopy, liver biopsy, and thoracoscopy using a ureteroscope [28, 29]. This group also reported combined transvesical and transgastric NOTES to perform cholecystectomy [30] and nephrectomy [23], although the latter was without specimen extraction. Our group

Figure 103.3 Transvesical visualization of liver and diaphragm using a rigid cystoscope in a 20-kg pig.

Figure 103.4 Pediatric gastroscope used for transvesical, transvaginal and transgastric NOTES.

has also performed transvesical peritoneoscopy using both the dual channel rigid cystoscope, including simple bowel manipulation [31], and the pediatric gastroscope (Figures 103.3–103.5). We also performed transurethral NOTES partial cystectomy with full-thickness bladder resection in the porcine model [25] (Figure 103.6).

Rectum/colon/intestine (transcolonic/transenteric)

An advantage of the rectum and colon as a natural orifice for NOTES access is its tolerance of relatively large scopes, such as colonoscopes. However, the high bacterial load of the colon makes this perhaps the most controversial access point, given the concern for potential infection, and it would require the ability to rigorously cleanse the bowel and effectively close the defect. Animal studies to date have included transcolonic cholecystectomy [32], ventral hernia repair, and distal pancreatectomy [33]. The only report of transcolonic access for a urologic procedure, to our knowledge, was

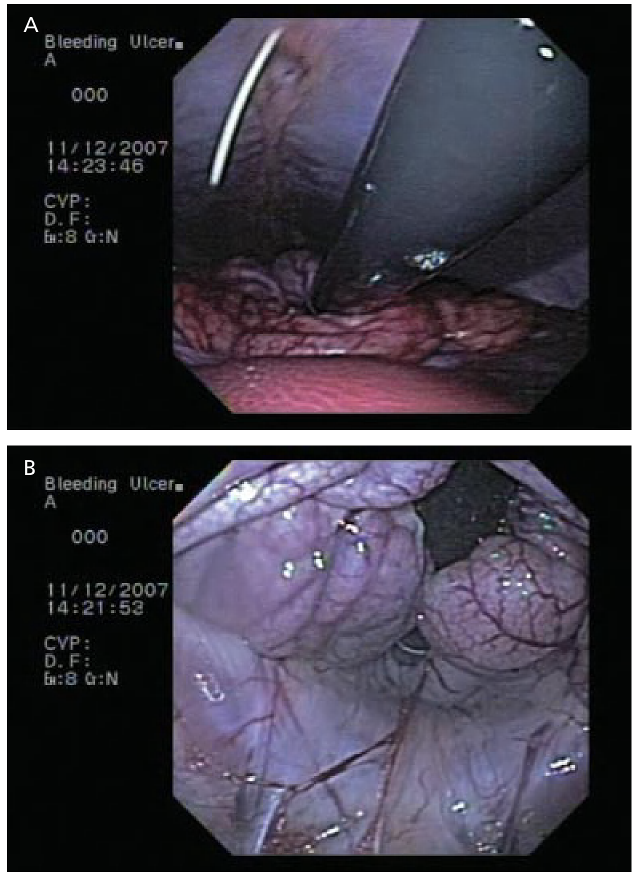

Figure 103.5 (A, B) Transvesical pediatric gastroscope in retroflexion, permitting visualization of the liver, bowel, and pelvis.

a hybrid NOTES nephrectomy by Box *et al*. in the porcine model [34]. This group used a da Vinci S robot (Intuitive Surgical, Sunnyvale, CA, USA) to perform nephrectomy with combined transvaginal, transcolonic, and a single transabdominal trocar with transvaginal specimen removal [34].

Technical challenges

NOSCAR produced a White Paper in 2006 that identified a number of specific barriers to NOTES procedures. Challenges that were identified at that time included peritoneal access, maintenance of spatial orientation, access closure, control of hemorrhage, and development of suturing and anastomotic devices. The need for development of a multitasking platform was also identified [11]. While the primary focus at that time was limited to access from the gastrointestinal tract, these same issues would apply to vaginal and bladder access as well.

One of the immediately obvious technical challenges of translumenal procedures is that with the single access, a coaxial approach is necessary, which entails using

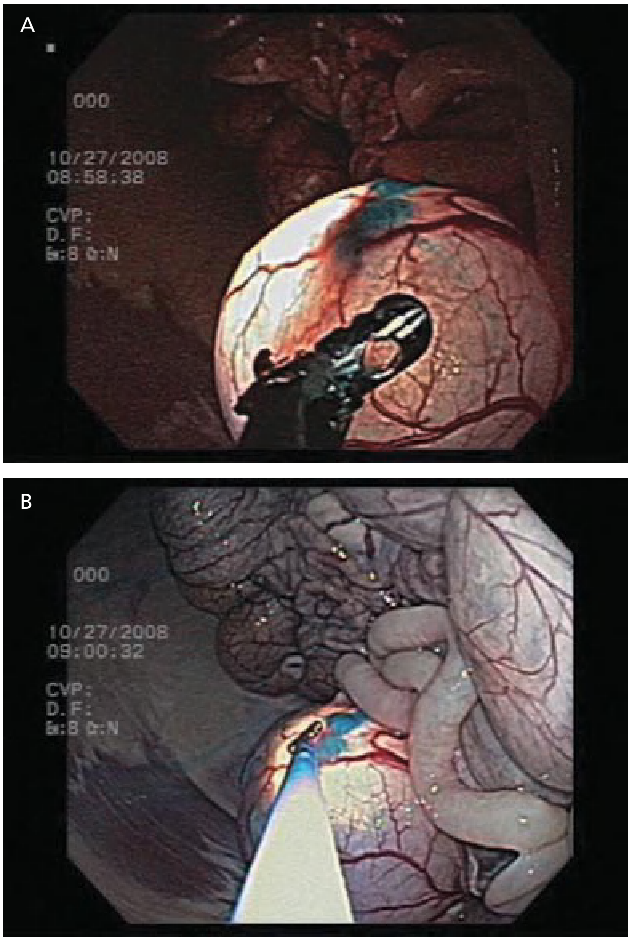

Figure 103.6 Transgastric NOTES Partial cystectomy using the R-Scope™ (Olympus, Tokyo, Japan) in the chronic porcine model. (A) Bladder is transilluminated with the cystoscope. Gastroscope bowel graspers are shown(B) An endoscopic loop is advanced to the bladder after preloading over the bowel grasper. Note that spatial orientation is difficult to maintain. In both these images the anterior abdominal wall is to the left and the fallopian tubes are to the upper right.

working instruments parallel to each other with limited ability to adjust the visual perspective. Urologists are already familiar with this concept, albeit to a lesser degree in the setting of bladder resections, stent removals, and ureteroscopic interventions such as basketing of stones. However, in contrast, all but the most basic therapeutic interventions typically require more than one instrument simultaneously, e.g. an instrument to retract while cutting.

Various strategies have been used for NOTES procedure to compensate for the coaxial limitations. One method is to obtain traditional triangulation by combining translumenal access points, such as combined transgastric and transvaginal access, or to use a hybrid NOTES approach. A disadvantage of the combined approach could include potential increased morbidity from additional access points and need for additional personnel.

Access

Establishing translumenal access while maintaining adequate sterility of the abdomen is a significant barrier, particularly for access from the gastrointestinal tract. The most clinically utilized translumenal access to date is transvaginal access, typically using a posterior colpotomy. Endoscopes can be inserted through the colpotomy and into the abdominal cavity either directly or with a preloaded overtube. An overtube allows easy reinsertion and exchange of instruments, although these are typically prototype devices, such as the modified trocar our group has used by attaching a plastic overtube to a standard laparoscopic trocar. The TriPort™ (Advanced Surgical Concepts, Wicklow, Ireland), for example, is a multiport device with a 15-mm gel valve and two 5-mm gel valves for laparoscopic instruments. The GelPort™ (Applied Medical) has also served as a multitrocar device for LESS procedures [35]. These combination devices have been used for some transvaginal NOTES procedures, including NOTES nephrectomy [36].

A modified PEG technique can be used for transgastric access with subsequent balloon dilation of the gastrotomy. For clinical use, this would likely require a multidisciplinary team that includes an endoscopist who is skilled with the gastrointestinal tract [13].)

Peritoneal access through the bladder is actually very simple to perform and could be the fastest method for access. Gettman and Blute described the initial human transvesical peritoneoscopy by introducing the ureteroscope after balloon dilation over a transvesical wire [26]. Our group routinely starts with a small incision in the porcine bladder using wire electrocautery, passing a wire through the vesicotomy, and then using balloon dilation over the wire to safely enlarge the incision with more control. However, a challenge using gas dilation of the bladder is a tendency for the bladder to collapse on itself if the defect is too large. In our experience, the porcine bladder is generally able to maintain its shape with dilation of the vesicotomy to 10 mm but not to 20 mm [37]. Lima's group used a 5.5-mm port for transvesical procedures using a ureteroscope in a porcine model [28], which is one approach to avoid the difficulty of bladder collapse and could allow periodic removal and insertion of the scope.

Establishing and maintaining pneumoperitoneum

Interestingly, for NOTES procedures, establishing and maintaining pneumoperitoneum has proven to be possible with even very small scopes such as the ureteroscope [26], pediatric gastroscope, and rigid cystoscope

[38]. However, in our experience, once instruments are inserted through the working channel, there can be a significant diminution in insufflation pressure, particularly with the smaller single channel scopes such as the pediatric gastroscope. There is also limited ability with current endoscope technology to regulate pressures, although some new platforms have addressed this problem. One solution is to use a transabdominal needle port for insufflation, although purists might consider this to be hybrid NOTES.

Use of conventional scopes

Much of the early work in NOTES has involved use of existing traditional endoscopic equipment. Important properties to consider in scope selection include scope size, flexibility, maneuverability, number of channels, channel size, ability to insufflate gas through the scope, ability to adequately illuminate the abdominal cavity, and ease of cleaning the lens. For most natural orifices, flexible scopes have proven to be advantageous and for transgastric access this property is essential to even reach the stomach perorally.

Most of the described scopes for transgastric or transvaginal access have been standard gastric endoscopes or colonoscopes with two channels, or pediatric gastroscopes with a single smaller channel. The standard gastric endoscopes have a number of advantages over other traditional scopes, including ability to maneuver both up/down and right/left separately, ability to self-clean the lens by depressing a button, and good illumination of the abdominal cavity.

Scope size is another important consideration. With the recent exception of procedures that used the combination port devices transvaginally, the scope is the sole conduit for instruments for most pure NOTES procedures to date. There is a tradeoff of between scope size and number and size of channels, as well as the size of the defect. We have found it is generally preferable to have at least two instrument channels that can accommodate standard endoscopic equipment for procedures that involve manipulation of tissues, assuming the scope is the only conduit for instruments. However, scope size affects possibilities for access. The small size of the urethra, for example, precludes introduction of even the smallest standard dual-channel adult gastric endoscope, although single channel pediatric gastroscopes can be used in our experience [38]. Very small scopes such as ureteroscopes introduced through the bladder may not even require closure of the defect [28].

Urologic scopes have had a more limited role to date, although a flexible cystoscope was described in Gettman *et al*.'s original paper for transvaginal access for nephrectomy [8]. Lima *et al*. described use of flexible ureteroscopes which are of ideal size but only accommodate small instruments [28], and our group described use of the standard rigid cystoscope, which provides reasonable illumination and two channels that each accommodate standard gastrointestinal endoscopic equipment [31]. Advantages of flexible scopes include maneuverability within the abdominal cavity and potential for retroflexion. For transvesical access, the standard gastroscope is too large for the urethra.

Additional challenges of traditional scopes include maintaining position of the scope as there is a tendency for the scope to recoil when pushing an instrument forward, which also affects transmission of forces. Spatial orientation can also be challenging with a tendency for flexible scopes, in particular, to rotate. This problem is most acutely obvious when the scope is retroflexed and the view may be turned completely upside down, which may be difficult or impossible to correct. As noted previously, traditional scopes often have coaxial limitations as well.

Endoscopic instruments

As with traditional open and laparoscopic surgeries, a variety of instruments are required to permit retraction, incising of tissue, dissection, and approximation of tissue. The challenge is to perform these tasks in a comparable manner to current standards with instruments that are small enough to fit through a small channel and which typically need to be flexible.

Grasping devices can be very helpful for manipulation of tissues. We have found the "rat-tooth" endoscopic forceps (FG-49L-1 grasping forceps; Olympus, Tokyo, Japan) to be helpful for manipulation of the bladder and bowel using the gastroscope and the rigid cystoscope (see Figure 103.6A). Endoscopic loop devices (e.g. Endoloop™; Ethicon Endo-Surgery, Cincinnati, OH, USA) can be used to entrap tissue prior to excision, such as a targeted area of bladder to be excised in NOTES partial cystectomy [25] (see Figure 103.6B)

Cutting of tissue with endoscopic instruments can be performed with needle knife electrocautery, snare wire cautery, or flexible endoscopic scissors. We have generally had better success with the first two options as the flexible endoscopic scissors have tended to be rather flimsy and difficult to use. It is hoped that industry may provide more robust scissors and other instruments in the future.

Several tools in the gastrointestinal endoscopic armamentarium are available for removing tissue. The most basic are a variety of flexible biopsy forceps similar to those used by the urologist cystoscopically, but with two basic differences: longer length to permit them to traverse the gastric endoscope and some have the ability to apply electrocautery directly with the forceps. As with cystoscopic biopsies in the bladder, these have a

limited role for obtaining very small samples of tissue. For removal of larger tissues, the rat-tooth forceps can be used to directly grasp tissue specimens that have already been excised [25]. Alternatively, there are various endoscopic specimen retrieval devices traditionally used in conjunction with colonoscopy or esophagogastroduodenoscopy (EGD) procedures that may be adapted for NOTES procedures, including the Roth Net™ (US Endoscopy, Mentor, OH, USA) and the Nakao SpiderNet™ (ConMed Endoscopic Technologies, Utica, NY, USA) [39, 40].

Because of the need both for closure of access points and to allow performance of many surgical procedures, tissue approximation has been one of the most intense areas of focus for development. A variety of devices have been described for these purposes. The ideal would be a device that would allow intracorporeal suturing with ease. An early prototype described in the literature was the Eagle Claw™ (Olympus). More recently, the Food and Drug Administration (FDA) approved the OverStitch™ device (Apollo Endosurgery, Austin, TX, USA), which is attached to the end of the gastroscope and allows both running and interrupted suture. Various other manufacturers have produced devices that are intended to substitute for suturing. These typically involve placement of a suture and then instead of tying a knot, a fastening device cinches the two sides of suture together. These include the T-Tag™ system and TAS™ Tissue Approximation System (Ethicon), EndoStitch™ (Covidien, Mansfield, MA, USA), and the NDO Surgical Plicator™ (NDO, Mansfield, MA, USA) [39, 41, 42].

A simple device that has been successfully used for tissue approximation (including closure of translumenal access) is the endoscopic clip. This was originally intended to provide hemostasis or mucosal approximation [37, 41]. While many of these clips can rotate, some clips such as the Resolution™ (Boston Scientific, Natick, MA, USA) can open and close multiple times before deployment, which allows the closure to be assessed before committing. Our group has successfully used these clips for closure of small bladder defects. However, we have had poor results with very large bladder defects in a study of transgastric partial cystectomies with a high rate of adhesions, pelvic abscesses, and premature demise in a chronic porcine model. Stapling devices have also been developed for NOTES procedures. Experimental devices include the Intelligent Natural Orifice Linear Cutter or iNOLC™ (Power Medical Interventions, Langhorne, PA, USA), which is a power-actuated linear stapler with a flexible shaft [43].

Closure of access

As described in the above section, a number of devices are being developed for tissue approximation. However, effective and safe closure of the access gastrotomy remains the most significant barrier to human applications of transgastric surgery since a gastric leak could be a devastating complication. Many of the devices have been used experimentally to this end, including endoscopic clips [25, 41], various suture devices [41], the NDO tissue plicating device [42], and the flexible stapler [43]. Similarly, a transcolonic access would need to be reliably closed due to the high bacterial load and risk of severe infections.

Transvaginal NOTES incisions, by contrast, are easily closed under direct vision using absorbable suture and appear to be well tolerated. In 2001, Gill *et al*. reported 10 cases of transvaginal extraction of kidneys in patients who had laparoscopic nephrectomies [44]. This group described excellent patient satisfaction on postoperative questionnaire and the only adverse event was self-limited vaginal spotting in a single patient In one early clinical experience of transvaginal NOTES cholecystectomy, four patients reported little discomfort and morbidity, including lack of dyspareunia [45].

Closure of transvesical NOTES access should be an area of particular interest to urologists and may also be relevant to treatment of traumatic and iatrogenic bladder injuries. Intraperitoneal bladder injuries typically require closure, although small vesicotomies can be managed with simple catheter drainage [26]. In the NOTES literature, Lima *et al*. reported no complications of the unclosed vesicotomy in a chronic transvesical NOTES study using the ureteroscope [28]. Reliable methods of closing the bladder defect endoscopically, however, would be ideal. To this end, Lima *et al*. demonstrated successful bladder closure using endoscopically applied sutures in a chronic porcine model [46]. Our group also described the successful use of standard gastrointestinal endoscopic clips for closure in a chronic porcine model [25], although duration of clip attachment and potential for stone formation are potential issues with this technique.

Novel platforms

Various novel platforms have been reported for NOTES. Of particular interest are endoscopic platforms specifically designed for NOTES procedures, robotic platforms, and intracorporeal instruments, whether taking the form of magnetic instruments or miniature intracorporeal robotics.

Dedicated NOTES scopes

Several scopes have been developed specifically for NOTES. Traditional gastric endoscopes, while potentially useful for translumenal procedures, were specifically designed for the specific purpose of working

within the lumen of the gastrointestinal tract and performance of relatively simple procedures such as removal of polyps. Meeting the new demands of NOTES for performance of complex procedures called for the development of new platforms with greater capabilities. A variety of concept scopes have been developed, including the Cobra™ (USGI Medical, San Clemente, CA, USA), which has three arms and the ability to lock shape, and the Viacath™ prototype scope (Hansen Medical, Mountain View, CA, USA) with articulating robotic arms [39]. Of the various new scopes, two in particular have reached commercial viability. The R-Scope™ (Olympus) resembles a standard gastroscope, but has two articulating sections and two elevators at the tip, one of which can be moved in the horizontal direction and the other in the vertical direction. The Transport™ (USGI Medical) can be locked into a given position, including in retroflexion, while maintaining the ability to steer the tip of the scope. The scope allows metered intraperitoneal insufflations and has two 6-mm and two 4-mm working channels [39]. Clayman *et al*. successfully used the Transport™ scope for a transvaginal NOTES nephrectomy in 2007 [47]. Certainly a concern with any novel platform will be the capital expense of new equipment for this purpose. The platforms developed to date are primarily applicable to transgastric, transvaginal, and perhaps transcolonic procedures, with no dedicated transvesical NOTES platforms described to our knowledge.

Robotic platform

The da Vinci robot (Intuitive Systems) has already been adapted for NOTES procedures, as previously noted for combined transvaginal and transcolonic hybrid NOTES nephrectomy [34] Haber *et al*. also reported use of the da Vinci system for transvaginal hybrid NOTES procedures, including nephrectomies, partial nephrectomies, and pyeloplasties [48]. While the da Vinci robot was not originally designed for NOTES, its use for this purpose is certainly a unique application of an existing technology. It can easily be envisioned that a future generation of robotics could be specifically designed for NOTES procedures. Canes *et al*. suggest there could be an increasing role for the robot in NOTES procedures, especially with further development of flexible robotics [49].

Internalized instrumentation

Instruments for laparoscopic and endoscopic procedures have always required both intracorporeal and extracorporeal portions in continuity, which limits the mobility and positioning of the internal portion. Two recent concepts have challenged the need for direct attachment between internal tools and the external means of manipulation with a new paradigm of independent internalized instruments: intracorporeal magnetic instruments and miniature internalized robots or "microrobots."

Magnetic instrumentation

A novel and exciting use of magnetic instrumentation was described by Cadeddu *et al*. [50]. Their "magnetic anchoring and guidance system" (MAGS) involves introducing instruments, such as cameras, graspers, and cautery instruments, through an incision and then manipulating them with an external electromagnetic coupling device. This MAGS system was successfully used in the laboratory for transvaginal NOTES nephrectomy and cholecystectomy, and for LESS nephrectomy. A magnetically anchored camera was used clinically for a LESS nephrectomy. The distance of the external coupler from the internal device can be a limitation, particularly in obese patients [50–54]. For NOTES procedures, the magnetic instruments would presumably be introduced through the natural orifice along with the scopes.

Miniature intracorporeal robotics

Miniature internalized robotic instruments may be mobile or stationary, but are controlled externally by remote control. Miniature robotic prototypes have typically had a single function, such as a camera, retraction or illumination [49]. Two camera prototypes have been described to assist laparoscopic prostatectomy in the laboratory. One prototype has a crawler functionality that provides internal mobility, while the other is stationary but provides a complete circumferential view of the abdomen [55]. These miniature robots have also been used in the setting of transgastric NOTES™ peritoneoscopy by Rentschler *et al*., who proposed using a "a family of robots" working in conjunction [56]. A current limitation of these robots is battery life, currently limited to less than 1 h [49]. While further development is likely required before application to the clinical setting, these prototypes do demonstrate proof of concept and are encouraging.

Conclusions

NOTES is an exciting new approach to minimally invasive surgery and represents the extreme in scarless surgery by performance of surgery without cutaneous incisions. The field of urology has the potential to be impacted either endogenously or exogenously by application of NOTES techniques. Urologists may continue to adapt laparoscopic urologic procedures to a NOTES approach, and they may also have a collaborative role in transvesical NOTES procedures for nonurologic

procedures (e.g. liver biopsies, gastric surgeries or cholecystectomies), potentially including transvesical access and closure and complication management. Additionally, many NOTES procedures may require collaboration of specialties that have not traditionally interacted, such as urologists and gastroenterologists.

It remains to be seen whether developments in LESS will be sufficiently channeled back to make NOTES in its purest form a viable clinical option in the future, and indeed whether potential advantages of NOTES could still outweigh any potential disadvantages of LESS. However, the recent description of a pure NOTES transvaginal nephrectomy in 2009 using a platform designed for LESS suggests that this could be the case [36].

Finally, there clearly are significant technical barriers to these approaches being adopted for widespread clinical use, despite promising early reports. Further developments have potential to overcome many of these challenges. We anticipate that various innovations will continue to be described both in the laboratory and clinically.

CHAPTER 104
NOTES: Access and Exit

Candace F. Granberg & Matthew T. Gettman
Department of Urology, Mayo Clinic, Rochester, MN, USA

Introduction

A paradigm shift in the approach to urologic surgery has occurred in recent years, with an ever-growing number of procedures being performed through fewer and smaller incisions. Natural orifice transluminal endoscopic surgery (NOTES) represents the next frontier in minimally invasive surgery. This approach permits access to the peritoneal or retroperitoneal cavity by making incisions in the stomach, bladder, or vagina rather than accessing the abdomen via skin incisions. Here, we detail the current understanding of access techniques utilized clinically and experimentally in transvaginal, transvesical, transgastric, and hybrid NOTES approaches. The chapter also highlights utilization of these approaches for urologic procedures as well as exit strategies for each approach.

Transvaginal NOTES

A transvaginal approach to surgery intuitively seems ideal, as many intra-abdominal organs can be accessed in a linear fashion. There have been several reports of successful urologic procedures performed transvaginally, with initial procedures tested in porcine models with subsequent transition to use in humans. In most described cases, pneumoperitoneum is acquired transabdominally through a Veress needle inserted through the umbilicus; however, it can also be achieved transvaginally after ports have been inserted through a direct vision colpotomy. For the exposure needed for transvaginal port placement, a combination of self-retaining vaginal retractors, Deaver retractors, and a weighted vaginal speculum may be used. A Foley catheter should be placed in all patients, and a rectal pack is optional. Multiple different ports and trocars have been used through the colpotomy with the transvaginal approach, as described below.

In 2002, Gettman *et al*. described transvaginal nephrectomy in a porcine model, the first experimental application of natural orifice surgery [1]. After establishing pneumoperitoneum transabdominally with a Veress needle, modified plastic fascial dilators traditionally used with the Amplatz dilating system (Microvasive; Boston Scientific Corporation, Natick, MA, USA) were used as transvaginal laparoscopic ports. The posterior colpotomy was balloon dilated to 24 F (UroMax II Plus, Microvasive) over a guidewire. A flexible cystoscope or standard 5-mm laparoscopic lens and camera were utilized transvaginally, and in some cases a traditional 5-mm transabdominal port was placed for the camera. Standard laparoscopic instruments and in some cases articulating instruments could be used through this access portal for dissection. The Endo-GIA stapler (US Surgical, Norwalk, CT, USA) was used transvaginally to divide hilar vessels and the ureter, and a 10-mm EndoCatch II device (US Surgical) was used to entrap the specimen.

Using a different platform, Clayman *et al*. also performed transvaginal nephrectomy in a porcine model

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

[2]. Again, pneumoperitoneum was obtained transabdominally with a Veress needle. Transvaginally, a TransPort Multi-Lumen Operating Platform (USGI Medical, San Clemente, CA, USA) with four working channels (two 4 mm, one 6 mm, one 7 mm) was placed through a posterior colpotomy incised with an endoscopic needle-knife (Cook Medical Inc, Bloomington, IN, USA). Tissue-acquisition devices (g-Prox and g-Lix; USGI Medical) were used via the TransPort for retraction in combination with other endoscopic instruments. An additional 12-mm transabdominal port was placed to maintain pneumoperitoneum, confirm placement during transvaginal access, place a fan retractor, and apply a vascular GIA (Ethicon Endo-Surgery Inc, Cincinnati, OH, USA) for division of the hilar vessels. Although the TransPort allowed for multiple instruments to be utilized through a single port, drawbacks with this experiment included difficulty with triangulation and inability to secure the renal hilum through the channels in this platform.

In the first published description of NOTES transvaginal nephrectomy in a human, Kaouk *et al*. utilized yet another transvaginal port [3]. Pneumoperitoneum was established via the umbilicus through a Veress needle. Initially, a multichannel single port (TriPort; Advanced Surgical Concepts, Wicklow, Ireland) was positioned across the vaginal wall; however, these authors noted significant instrument clashing and subsequently exchanged the port for a GelPort (Applied Medical, Rancho Santa Margarita, CA, USA). Through this port, multiple trocars could be placed, which allowed for use of articulating instruments, a Hem-O-lok clip applier (Weck Closure Systems, Research Triangle Park, NC, USA), an endovascular stapler, and a laparoscopic retrieval bag.

In a cadaver study, Aron *et al*. utilized the QuadPort (Advanced Surgical Concepts) via a 3-cm colpotomy to perform transvaginal nephrectomy [4]. This port has an inner ring that is placed through the colpotomy and deployed to retain the port in place. The external ring is then cinched over the vulva, and these authors excised the redundant portion of the plastic sleeve. Pneumoperitoneum was then achieved through the gas inlet of the QuadPort. The channels in this port include one of 15 mm, two of 10 mm, and one of 5 mm. Through these channels, the authors used conventional straight and articulating laparoscopic instruments, with the endoscope placed through one of the 10 mm channels.

Another novel approach to transvaginal surgery includes incorporation of a magnetic anchoring and guidance system (MAGS), as described by Raman *et al.* for transvaginal NOTES nephrectomy in porcine models [5]. In this study, a 2-cm vaginotomy was made with electrocautery, blunt dissection was performed to create the rectovaginal space, the peritoneum was incised under direct vision via a gastroscope, and the gastroscope was advanced into the peritoneal cavity to allow air through the scope to create pneumoperitoneum. A rigid access port with a 26-mm outer diameter and 40-cm length was placed over a wire to replace the gastroscope, and the MAGS camera and cauterizer were deployed through the port. The MAGS system allows for manipulation of the camera and cauterizer independent of the transvaginal instruments, avoiding the "sword-fighting" of instruments traditionally encountered with single-port transvaginal access.

Transvesical NOTES

Similar to the transvaginal approach, the transvesical route obviates the limits of spatial orientation by allowing straight-line access to intraperitoneal organs. Clear limitations to the transvesical approach exist, including urethral diameter, urethral length, and potential need for urethral dilation with its inherent risks. There are few reports of pure transvesical NOTES; the access methods used are described here.

Use of the bladder as a portal of entry for NOTES was demonstrated in eight female pigs by Lima *et al.* in 2006 [6]. Under ureteroscopic guidance, the bladder was incised with Olympus A2576 scissors placed through the working channel of the ureteroscope. Next, a 5F open-ended ureteral catheter was advanced through the incision into the peritoneal cavity. Over a guidewire placed through the ureteral catheter, the cystotomy was dilated using the dilator of an ureterorenoscope sheath (Microvasive; Boston Scientific Corporation) encased by a flexible overtube. The ureteroscope could subsequently be passed through the overtube into the peritoneum, through which an Olympus UHI-3 insufflator was used to create pneumoperitoneum.

The first documented case of a clinical application of transvesical NOTES was performed by Gettman and Blute in a 56-year-old man prior to robotic prostatectomy [7]. With the patient in steep Trendelenburg position, a standard rigid cystoscope was placed transurethrally and a flexible injection needle was advanced through the bladder wall under simultaneous laparoscopic and endoscopic guidance (Figure 104.1). A balloon dilator (UroMax; Boston Scientific Corporation) was used to dilate the cystotomy tract. A flexible ureteroscope (DUR-8) was introduced through the cystotomy tract and transvesical peritoneoscopy was performed (Figure 104.2). Insufflation was successfully performed through the working channel of the ureteroscope to maintain pneumoperitoneum, and all intraperitoneal structures were visualized with a direct line of sight. After removing the ureteroscope, the cystotomy site did decrease in size but was not watertight; thus,

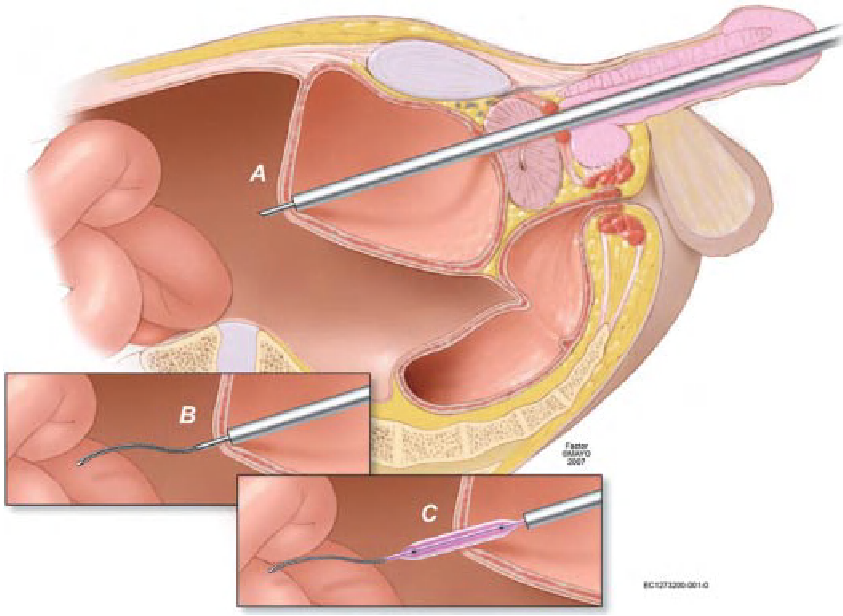

Figure 104.1 (A) Standard rigid cystoscopy with a flexible injection needle advanced through the bladder wall. (B) A guidewire is advanced through the injection needle and (C) balloon dilation is performed to dilate the cystotomy tract. (Reproduced from Lima, E. *et al*. Endoscopic Closure of Transmural Bladder Wall Perforations, *European Urology* 2009; 56:1, with permission.)

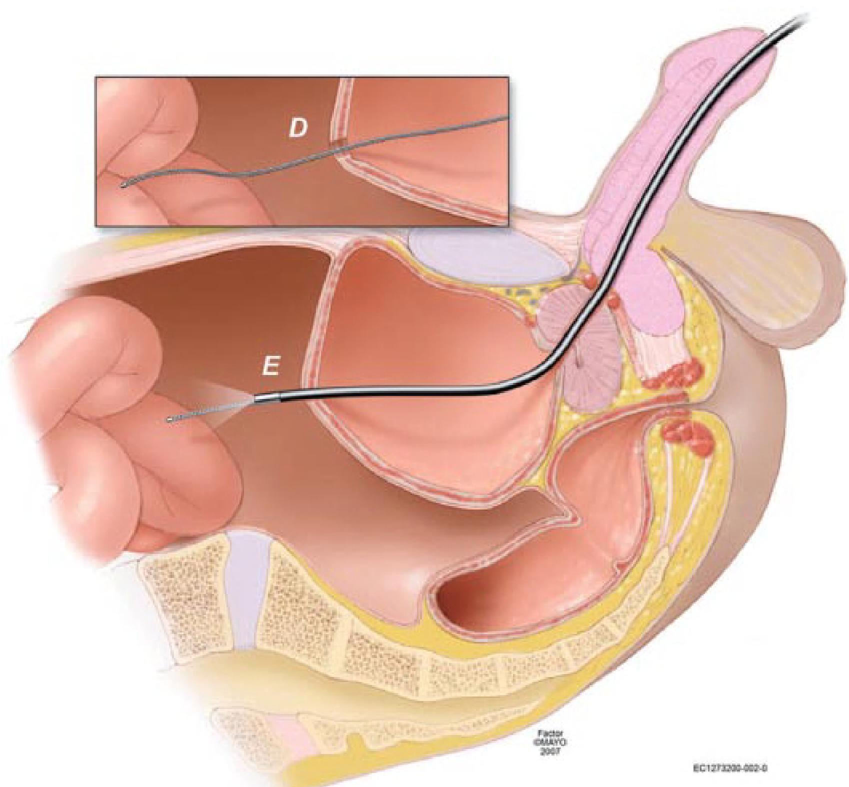

Figure 104.2 A DUR-8 flexible ureteroscope is advanced into the peritoneal cavity over the guidewire (courtesy of Mayo-Rochester).

the site was closed with 2-0 Vicryl figure-of-eight sutures through laparoscopic ports.

Another urologic application of transvesical NOTES was described by Humphreys *et al*. to perform radical prostatectomy [8]. Access in this report consisted of urethral dilation to 30 F and placement of a continuous-flow 26 F resectoscope. A 100-W holmium: YAG laser was used to incise carefully through the capsule for extraprostatic dissection. In this approach, the neurovascular bundles and dorsal venous complex were spared. After completing dissection, the specimen was pushed into the bladder, morcellated, and vesicourethral anastomosis was performed using an offset nephroscope.

Transgastric NOTES

There is a risk of intraperitoneal contamination and infection due to exposure to gastric and bowel contents with oral approaches. Thus, many surgeons irrigate the stomach with saline or a disinfectant solution prior to puncturing or incising the gastric wall. Another limitation of gastric access is the inability to maintain spatial orientation. All instruments pass through working channels on the endoscope, with the light source and camera in line. During transgastric NOTES procedures, for example, some maneuvers require working off-axis, which further increases the difficulty of complex procedures. Most urologic applications for transgastric NOTES are in the setting of hybrid NOTES approaches, described below.

One gastric access technique, known as a blind needle-knife puncture [9, 10], begins with perforating the stomach on the anterior wall with a needle-knife or electrocautery under direct vision via gastroscope. Next, a guidewire is passed into the peritoneal cavity. The gastrotomy is then extended with an electrosurgical knife, sphincterotome, or a dilation balloon. After placing an endoscope (which can also be placed through an overtube), pneumoperitoneum is established with a laparoscopic insufflator connected to the accessory channel of the endoscope. In the balloon gastrotomy technique [10, 11], the gastrotomy puncture site is enlarged with a radially-expanding 20-mm balloon dilator, with subsequent advancement of the endoscope into the peritoneal cavity. Anterior wall access is preferred so as not to incur surrounding organ injury. A technical advantage of balloon gastrotomy versus a cut gastrotomy is a reduced risk of bleeding, as an expansile disruption of gastric tissue may be less traumatic to blood vessels. A limitation of this access technique is difficulty maintaining insufflation due to air leakage through the gastrotomy site.

Another technique, termed submucosal endoscopy with mucosal flap (SEMF), utilizes the submucosa of the gastric wall as a working space [12–14]. First, saline is injected to raise a submucosal bleb through which high-pressure bursts of CO_2 create a space in which blunt dissection is then used to separate the mucosa from the circular muscle layer. The submucosal space is then entered with the endoscope, and this is tunneled from 4 to 8 cm, and at the distal end of the tract a needle-knife is used to incise the seromuscular layer and the peritoneum is entered.

Crouzet *et al*. described renal cryoablation via transgastric access in a porcine model [15]. Pneumoperitoneum was first established transabdominally using a Veress needle. Next, gastrotomy was created by incising with the needle-knife followed by radially dilating with a 15-mm dilating balloon over a guidewire. A dual-channel video gastroscope (Olympus America Corporation, Center Valley, PA, USA) with an outer diameter of 13.2 mm and instrument channels of 2.8 and 3.7 mm was advanced. After dissecting through the gastroscope, cryoablation was performed percutaneously under gastroscopic vision.

Another group reported the feasibility of partial nephrectomy through a transgastric approach in a porcine model [16]. Pneumoperitoneum was gained using a transabdominal Veress needle, and a 2-cm gastrotomy was created using a diathermy electrocautery needle under gastroscopic guidance. This gastroscope (Olympus GIF-2T160) had an outer diameter of 12.6 mm and working channels of 3.7 and 2.8 mm, and could flex 210°, 90° down vertically, and 100° horizontally in each direction. After advancing the scope through the gastrotomy, a thulium laser (RevoLix; AllMed Systems, Pleasanton, CA, USA) was used to perform partial nephrectomy without hilar clamping.

Partial cystectomy via transgastric access was also reported to be successful by Sawyer *et al*. [17]. After needle-knife incision and advancement of a gastroscope near the bladder, endoscopic loop devices placed through working channels were closed to envelop the bladder specimen, and a needle knife and wire snare were used to cauterize an incision between the closed loops. The specimen was grasped and removed through the gastrotomy site.

Hybrid NOTES

There are many benefits to utilizing multiple natural orifices as access ports, termed hybrid NOTES surgery. Both portals can be used for introducing cameras, insufflation, and importantly instruments, overcoming the obstacle of lack of triangulation encountered in some single-access NOTES portals. Moreover, if one access portal precludes placement of certain instruments due to size limitations, use of an additional another access portal can allow for access.

Using a combined transgastric and transvesical approach, Lima *et al*. reported successful porcine nephrectomy [18]. A 5-mm camera was first placed transvesically using the access technique of Lima *et al*. [6], described above. Gastrotomy was established on the anterior wall with a needle-knife and cautery, and enlarged subsequently with a papillotomy knife. By alternating a rigid Olympus A2942A ureteroscope transvesically and a double-channel Olympus GIF-2T160 endoscope transgastrically, the working channels of both portals were able to be used for instrumentation. UltraCision Harmonic Scalpel Long Shears ultrasonic scissors were used via the transvesical port for dividing the renal artery and vein. In two animals, the ultrasonic scissors were insufficient to control the vessels, and a Ligamax five-clip applicator was successfully used to place clips for hemostasis. A major limitation in this study was the inability to close the gastrotomy portal safely. Additionally, instrumentation was limited for extraction; thus specimens were left *in situ*.

Isariyawongse *et al*. built on this concept, performing nephrectomy via a hybrid transgastric and transvaginal approach in a porcine model [19]. Transgastric access was obtained first, with subsequent pneumoperitoneum established through a single-lumen therapeutic gastroscope (Olympus EVIS Type 100 Q140). Under transgastric visual guidance, needle-knife electrocautery was used to create a transvaginal port for a 5.9-mm single-channel pediatric gastroscope (Olympus GIF XP-160). A novel laparoscopic trocar/endoscopic overtube was advanced over the transvaginal endoscope as the NOTES port and portal for continued insufflation. Standard laparoscopic instruments were used for dissection, and an Endo-GIA Universal 12-mm stapler (Autosuture, Covidien, Mansfield, MA, USA) was successfully used via the transvaginal trocar to divide the hilar vessels and ureter. The specimen was entrapped in a retrieval device (Endocatch Gold 10 mm; Autosuture) and removed through the vaginal incision.

The success of robot-assisted laparoscopic surgery as applied to urologic procedures prompted Box *et al.* to attempt a robot-assisted hybrid NOTES nephrectomy in a female pig [20]. A 12-mm transabdominal port was placed midline for use of the robotic camera as well as maintaining pneumoperitoneum. Two 12-mm standard laparoscopic ports (Ethicon Endo-Surgery Inc) were placed through the vagina and colon, with robotic ports telescoped through these ports upon docking of the robot. Robotic instruments (HotShears and ProGrasp) were used for dissection, and the hilum was divided using a vascular Endo-GIA stapler via the transvaginal port. The specimen was withdrawn through the vaginal incision. A significant limitation in this study was difficulty with robotic arm movement due to the proximity of the ports, which led to frequent collisions and "sword-fighting."

Haber *et al.* sought to overcome the lack of triangulation in previous NOTES procedures necessary for suturing by applying the robot to a hybrid transabdominal single port with a transvaginal port for dismembered pyeloplasty, partial nephrectomy, and radical nephrectomy in porcine models [21]. The transabdominal port consisted of either a single port with three channels (Uni-X; Pnavel Systems, Brooklyn, NY, USA) placed in the umbilicus or two ports (12-mm standard trocar and 8-mm robotic trocar) placed through a single 2-cm umbilical incision. Under laparoscopic vision, a flexible 12-mm cannula 20 cm long (US Endoscopy, Mentor, OH, USA) was placed as a transvaginal port, to which a robotic arm was attached. For pyeloplasty, EndoWrist needle drivers (Intuitive Surgical Inc, Sunnyvale, CA, USA) were used for the anastomosis. For radical nephrectomy, the renal artery was clipped and divided, and an XL Endo-GIA stapler (Covidien) was used to control the renal vein, with introduction of the clip applier and stapler via the vaginal port. For partial nephrectomy, the vaginal port served as an access point for introducing sutures, bolsters, and a laparoscopic bulldog (MicroFrance) for vascular control and renorrhaphy. Although collisions between the umbilical robotic arm and laparoscope still occurred in number of the cases due to their parallel alignment, the addition of the robot to NOTES provided a great advantage in providing three-dimensional vision, articulating instruments, and improved ability for intracorporeal suturing.

Exit strategies

Specimen extraction is an obvious limitation of NOTES procedures. A pure transgastric or transvesical approach may be ideal for purely reconstructive procedures, however extracting any sizable specimen through these portals is nearly impossible. Thus, alternative exit sites must be used. Additionally reliable closure techniques must be established.

Transvaginal exit strategies

A major benefit to transvaginal extraction is that a colpotomy can be extended to accommodate the size of the specimen, to a certain extent. However, this extraction technique is not only limited to female patients, but is typically excluded in those females who have had previous vaginal or pelvic surgery and in whom dissection may be limited by adhesions.

In the surviving animals in Gettman *et al.*'s initial porcine nephrectomy experiment, the vaginal incision was not closed but was left to heal by secondary

intention due to small caliber and difficulty of closure with standard open techniques. Inspection of the incisions 1 week postoperatively revealed that the incisions had healed well [1]. However, concern exists regarding bacterial seeding of the peritoneal cavity and consequentially, infectious complications. Thus, the colpotomy is typically closed by hand in a single layer under direct vision, as has been done by gynecologists for years.

Transvesical exit strategies

A major limitation of utilizing the urethra as an access portal is size, which precludes extraction of large specimens. Additionally, potential risks of transvesical NOTES include fistula formation, infection, and peritonitis. Moreover, the effect of pneumoperitoneum in the urinary tract on kidney and bladder function is largely unknown.

Reliable bladder closure is also a concern with transvesical access. In most transvesical animal experiments, bladder closure was not attempted and the catheter was simply left in place. At necroscopy, it was observed that the vesicotomy sites had healed completely [6, 17, 18]. However, due to the concerns noted regarding fistula and infection, a dependable closure technique for the vesicotomy must be established. Furthermore, if primary healing of a vesicotomy is used, the benefits of a transvesical approach must be weighed against the morbidity of prolonged postoperative catheterization in patients.

Metzelder *et al.* described a technique for vesicotomy closure in piglets after transurethral NOTES nephrectomy [22]. A caveat to this closure is that it was not performed purely transvesically; rather, the procedure utilized a hybrid transumbilical and transvesical approach, and at the conclusion of the procedure an Endoloop device was used to close the bladder, while a 2-mm transurethral endoscopic clamp was used for assistance. At necroscopy, adequate bladder closure was tested using air-filling pressures and all closures were found to be impermeable.

Transgastric exit strategies

When transgastric NOTES initially emerged, there was significant concern for postoperative leak, fistula formation, and infection due to lack of adequate closure techniques. Although endoclips were initially used, this method typically only achieved mucosal closure. This technique has been employed in the submucosal tunneling approach [12]. However, full-thickness closure is the standard of care to prevent complications. Subsequently, several authors have reported on various gastrotomy closure techniques utilizing novel devices.

One group compared endoscopic clips versus over-the-scope clips (OTSC; Ovesco Endoscopy, Tübingen, Germany) for closure of an 18-mm gastrotomy in a porcine cohort [23]. Endoclips were applied through a double channel endoscope utilizing an Ovesco Twin Grasper (OTSC; Ovesco Endocopy) and Resolution clips (Boston Scientific Corporation). The OTSC technique employs traumatic gastric closure OTSCs, which have longer spikes that allow for anchoring of tissue. This group found that not only did the OTSC technique take significantly less time as compared to standard endoclips (mean 8.5 min vs 31.5 min, respectively), but the latter technique had an increased risk of leakage and intra-abdominal infections.

Full-thickness closure has been described using multiple different suturing devices. A suturing technology first described by Swain in 2003 involved a series of double T-tags positioned around the defect and advanced through the gastric wall [24]. The tags were approximated in pairs and locked to close the gastrotomy. This technique as well as its variations, although proven to provide an effective closure, was considered dangerous secondary to potential for inadvertent injury to surrounding organs [25, 26].

Desilets *et al*. described a modified T-anchor technique for closing the gastrotomy in a purse-string fashion in ex vivo porcine stomachs [27]. Metal wire loops were attached to T-anchors along which a 2-0 nylon suture was strung. Endoscopically, a transmural closure was achieved by placing the anchors into a slotted 19 G needle that had been advanced through the gastric wall, and pushing the anchor out of the needle with an inner stylet. By placing the anchors in a square around the gastrotomy, pulling tension, and applying a friction-fit collar and crimping device (Cook Endoscopy, Winston-Salem, NC, USA), the purse-string closure was completed. Another purse-string type of closure utilizes a device, Purse String Suturing (LSI Solutions, Victor, NY, USA), to aspirate the tissue containing the defect into a chamber, which invaginates the tissue [28]. Needles are then advanced through the tissue, creating a purse-string closure.

Another described gastrotomy closure method utilized a double-Endoloop technique (HX-400U-30; Olympus) in a porcine model [29]. Through a standard endoscope, an endoscopic grasper was advanced through an open Endoloop and one incisional edge was grasped and brought through the Endoloop, and the Endoloop was closed and released. This was repeated with the other edge of the incision, bringing the Endoloop around the stock of the first Endoloop. By tightening the second Endoloop, edges were reapproximated. The closure was tested with insufflation and found to be airtight. At necroscopy, evaluation of the closure sites found them to be well-healed without evidence of leak.

The Eagle Claw (Olympus), developed by the Apollo group, consists of a detachable needle attached to a curved holder with a mounted 3-0 nylon stitch. With jaw opposition, the defect is brought together by passing a needle through the tissue under direct endoscopic vision. The needle is then detached and the plication is completed by tightening the suture [30].

Stapling devices have also been used for gastrotomy closure. A linear stapler system (Surgassist; Power Medical Interventions, Langhorne, USA) consists of a flexible, 13-mm diameter shaft with a 55-mm stapler magazine which is deployed via an electronically controlled remote. Although closure has proven effective in *ex vivo* applications, a limitation of this device lies in the difficulty of manipulating tissue within the branches of the stapler [31]. Sherwinter *et al*. have subsequently reported on a modified circular stapler, a Surgassist powered circular stapler with a 213-cm flexible shaft [32]. A custom PVC auger-shaped tip attached to the anvil dilates the gastrotomy and allows the gastric wall to be loaded between the anvil and the staple cartridge. A novel modification of the device was to cover the staple cartridge with a loop of suture held in place by absorbable Vicryl mesh. After firing the stapler, the mesh is affixed to the outer portion of the viscerotomy, and the suture has been prepared for use as a purse-string closure. At the conclusion of the procedure, the suture is cinched under direct vision and locked using an endoscopic knotting device (TAS; Ethicon Endo-Surgery Inc).

Conclusions

Significant strides have been made in recent years in developing novel instrumentation to enhance NOTES procedures. The choice of access portal must be individualized to the organ of interest, need for specimen extraction, and obviously surgeon's expertise, as each orifice has inherent anatomic and technical limitations. Reliable closure of the access portal is another fundamental need with NOTES. In this regard, multiple innovative strategies have been introduced and evaluated both clinically and experimentally. For the future, clinical acceptance of NOTES will be in part dependent on the fundamental issues of safe entry to the abdomen and reliable closure of the access portal.

Department of Urology, The Ohio State University, Columbus, OH, USA

Introduction

Natural orifice translumenal endoscopic surgery (NOTES) has been gaining exposure and garnering more interest as an alternative, potentially less invasive approach to surgery. By performing surgery via a natural orifice, visible scars are eliminated, providing an obvious cosmetic benefit in addition to several theoretical benefits such as decreased pain, elimination of abdominal wall complications, and easier access (particularly in obese patients). This chapter will focus on the current clinical experience with NOTES in urology.

History

Performing surgery via a natural orifice is not new and in fact this dates back over a century. Gynecologists were gaining peritoneal access via the vagina to perform culdoscopy in the 1920s [1]. Urologists have been pioneers in natural orifice surgery, making a debut with transurethral surgery in 1877 with Nitze's cystoscope and in 1926 with endoscopic resection of bladder tumors [2, 3]. NOTES requires the intentional puncture of a hollow viscera in order to enter an otherwise inaccessible body cavity, so the aforementioned transurethral procedures would not be considered NOTES, but these experiences have served as part of the foundation for transluminal procedures [4]. It is the pioneering spirit of the urologic community that has kept urologic surgeons at the forefront of discovery and innovation, allowing them to continue to "push the envelope" and NOTES is no exception.

Transition to NOTES

The technical challenges encountered when performing NOTES using currently available instrumentation have been extensively described and include those secondary to the parallel insertion of instruments with a lack of triangulation, maintaining spatial orientation, inefficient traction, and indirect force transmission. As with any major change in surgical technique, there are several necessary transitions that should be undertaken to ensure the appropriate safety and efficacy of the technique. Experimental work in the lab on inanimate and animate models is necessary to demonstrate a reasonable level of feasibility. Ideally, this is followed by cadaveric studies to document this feasibility with more complex human anatomy. Finally, a careful stepwise clinical introduction should be undertaken. In general, this is the transition that has been seen with the clinical introduction of NOTES in urology.

Use of natural orifices: initial clinical experience

NOTES is certainly in its infancy as a surgical approach. As a result, most of the clinical reports in urology are either case reports or very small series. This section will

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

review the published clinical applications of NOTES in urology.

Nomenclature

With any surgical procedure, new or old, there are invariably a variety of techniques and approaches to perform any given surgery. It becomes important to establish a standard nomenclature to ensure there is consistent and accurate reporting in the literature. This serves to both assist with future literature searches and to allow for a more appropriate comparison of techniques. The NOTES and LESS Working Group attempted to address these issues and have published a white paper on nomenclature [4]. NOTES was defined as a surgical procedure that utilizes one or more patent natural orifices of the body with the intention to puncture a hollow viscus in order to enter an otherwise inaccessible body cavity without the use of any transabdominal instrumentation. A procedure is considered hybrid NOTES if most of the procedure is performed via a natural orifice, but a transabdominal port is used at some point during the surgery. If a natural orifice is used as an additional port during laparoscopic surgery for insertion of an instrument or an endoscope for visualization, this is designated NOTES-assisted surgery. There is a logical stepwise progression from NOTES-assisted to hybrid NOTES to a "pure" NOTES surgical procedure as the level of difficulty can be expected to increase.

Urology and NOTES access

NOTES requires the surgeon to puncture an otherwise normal organ, which begs the question as to whether this is a reasonable thing to do. Aside from the extensive experience with transurethral surgery, urologists have also published several clinical reports of other organs serving as an entry portal for NOTES. These reports provide preliminary data to the feasibility and safety of a transluminal approach.

Bladder

The bladder is the obvious access portal for urologic investigation. Gettman and Blute were the first to report the clinical application of the bladder as a potential portal for NOTES [5]. At the time of robotic prostatectomy, under an Institutional Review Board (IRB)-approved protocol, a rigid cystoscope was use to advance an injection needle through the dome of the bladder under laparoscopic guidance. A guidewire was advanced through the needle and the opening was balloon dilated, which allowed for the introduction of a flexible ureteroscope into the peritoneal cavity. Peritonoscopy was performed and all intraperitoneal organs and structures could be visualized while maintaining the pneumoperitoneum via the working channel of the ureteroscope.

Vagina

The first transvaginal extraction of a nephrectomy specimen dates back to the early 1990s [6, 7]. A more recent experience was described by Gill *et al.*, who reported on a series of 10 patients who underwent laparoscopic nephrectomies with transvaginal specimen extraction [8]. The extraction added 35 min to the procedure, in large part because of the need to reposition the patient from the flank to the lithotomy position to retrieve the specimen. This was well tolerated by these women, who reported minimal discomfort related to the vaginal incision; in fact, all patients indicated their abdominal port sites were more painful that the vaginal extraction site. Furthermore, none of the sexually active women reported any change in their postoperative sexual function.

Colon

The urologic literature also contains some support for the use of a transcolonic approach. Degar *et al.* reported on a series of patients undergoing laparoscopic radical cystectomy with an intracorporeal rectosigmoid pouch [9]. There were six male patients in this series who had the specimen removed via the rectum. There were no reported infectious complications or any complications thought to be related to the transrectal specimen removal.

NOTES cadaver model

Aron *et al.* reported their experience with transvaginal NOTES nephrectomy using a multichannel port in a human cadaver model [10]. They planned to perform four transvaginal nephrectomies (two right and two left) on four fresh female cadavers. The cadavers were placed in the lithotomy position and a TriPort (Advanced Surgical Concepts, Wicklow, Ireland) was placed at the umbilicus to monitor the transvaginal procedure. A steep Trendelenburg was maintained as a posterior colpotomy was performed through which a four-channel QuadPort (Advanced Surgical Concepts) was inserted. The cadaver was then rotated 30–45° lateral, and standard and articulating laparoscopic instruments were placed through the QuadPort to perform the procedure. The authors commented on the difficulty in dissecting the upper pole of the kidney, in part because of the suboptimal visualization from the transvaginal portal and also from adhesions from previous surgery in two of the cadavers. Because of these difficulties, some

(~10%) of the procedure was completed via the transumbilical portal in both of the right nephrectomies. One of the attempted left nephrectomies was abandoned secondary to dense intra-abdominal adhesions from prior surgery. The other left-sided nephrectomy was completed with only transvaginal instrumentation as no transabdominal ports or instruments were used. The previously encountered problem with upper pole visualization was overcome by using a flexible gastroscope and bariatric length instruments during this step of the procedure. A standard laparoscopic stapler was used to divide the hilum in all cases followed by placement into a 15-mm retrieval bag and intact specimen extraction. The vaginal port placement took 20 min for the first case, but had decreased to 5 min by the last case. The nephrectomy portion of the procedure was completed in 115–133 min (mean total operative duration 170 min). The authors were able to complete a transvaginal NOTES nephrectomy in a cadaver without any transabdominal instrumentation. Some limitations were noted, including difficulties maintaining the pneumoperitoneum with the transvaginally placed QuadPort, particularly when a uterus was present. They demonstrated the feasibility of using conventional rigid laparoscopic instruments with a transvaginal approach, which overcome many of the limitations seen with flexible instrumentation, such as inefficient traction and indirect force transmission.

Clinical applications (Table 105.1)

NOTES-assisted procedures

NOTES-assisted surgery is a logical beginning in the ultimate journey to NOTES. Branco *et al.* reported a case of transvaginal NOTES-assisted laparoscopic nephrectomy [11]. In this case report, a 23-year-old woman with right flank pain and recurrent infections was found to have a nonfunctional right kidney and elected to undergo surgical removal. The procedure was performed with two 5-mm transabdominal ports, and visualization was provided with a flexible endoscope placed transvaginally via a posterior colpotomy, which was extended for specimen removal. No transvaginal port was utilized as the endoscope was placed directly through the colpotomy. The procedure was completed in 170 min with an estimated blood loss (EBL) of 350 mL. The patient had no complications and was discharged 12 h after the procedure, returning to normal activity on postoperative day 3. The authors noted difficulties with the flexible endoscope in terms of maintaining orientation and keeping the surgical field in view.

Alcaraz *et al.* reported a series of transvaginal NOTES-assisted laparoscopic nephrectomies [12]. Similar to the above case report, the authors used two transabdominal ports (one 5 mm and one 10 mm) in addition to a special bariatric trocar that was placed transvaginally. Visualization was provided with a deflectable-tip laparoscope placed via the transvaginal trocar. The procedure was completed in standard laparoscopic fashion with instruments placed through the transabdominal ports. The kidney was removed through the vagina after the posterior vaginal wall incision was extended; this was then closed with conventional instruments. Fourteen women underwent this procedure for a total of seven right and seven left nephrectomies with a mean operative time of 133 min and a mean EBL of 111 mL. One patient had a colon injury that required a diverting colostomy. The authors attributed this injury to multiple adhesions from previous surgery and did not think it was related to the placement or use of the transvaginal portal, but did highlight the importance of patient selection. Furthermore, they also noted difficulty retrieving the specimen transvaginally in patients who had a body mass index (BMI) greater than 30.

These reports help to establish the vagina as a viable portal and extraction site for NOTES. The NOTES-assisted approach allows surgeons to use a natural orifice as a portal through which to place an instrument or endoscope during a laparoscopic procedure, allowing them to become more familiar with the access and closure, while maintaining the ability to perform the surgery with standard laparoscopic techniques.

Hybrid NOTES

The next step in the transition to a completely NOTES approach is hybrid NOTES. Kaouk *et al.* reported a transvaginal hybrid NOTES nephrectomy in a 57-year-old woman with a right-sided atrophic kidney who was experiencing flank pain and elected to proceed with a transvaginal nephrectomy [13]. Insufflation was achieved with a Veress needle placed at the umbilicus. Following establishment of pneumoperitoneum, a posterior colpotomy was made. A previous hysterectomy had left many pelvic adhesions, so a 5-mm transabdominal port was placed at the umbilicus in order to place the transvaginal port under direct vision. A TriPort was placed transvaginally and the procedure was performed using a 5-mm 0° flexible-tip laparoscope, and 45-cm articulating laparoscopic instruments. During the dissection, ergonomic constraints were noted from the TriPort, so this was exchanged for a GelPort (Applied Medical, Rancho Santa Margarita, CA, USA) with a 12-mm and two 5-mm ports placed through it. The ureter was divided with clips and the renal vessels were individually divided with an endovascular stapler. In order to safely expose the hilum, the 5-mm transabdominal port was used to retract the colon during this

Table 105.1 Summary of clinical series of urologic transvaginal NOTES procedures.

BMI, body mass index; EBL, estimated blood loss.

step. The rest of the kidney was freed with the use of an extra-long (65 cm) monopolar hook and placed into a retrieval bag, which was removed via the vaginal incision. The colpotomy was closed directly with Vicryl sutures. The surgery was completed in 307 min (124 min to obtain vaginal access). There were no complications and the EBL was 100 mL. The patient did well postoperatively and was discharged home on postoperative day 1.

Sotelo *et al.* described their experience with a hybrid NOTES transvaginal radical nephrectomy in a 65-year-old woman who was diagnosed with an incidental 6-cm enhancing central mass in the lower pole of the left kidney [14]. The patient was placed in lithotomy with a 45° right lateral decubitus position. At the start of the procedure, a TriPort was placed at the umbilicus. The posterior vaginal fornix was then entered using transabdominally placed laparoscopic instruments. A second TriPort was placed transvaginally and used to perform the majority of the dissection. A 5-mm 0° flexible-tip laparoscope was used to provide visualization and a combination of standard and articulating laparoscopic instruments were used to perform the procedure. The hilar dissection was performed utilizing the transumbilical portal for the camera and some laparoscopic assistance. The artery and vein were divided individually with clips and a vascular stapler, respectively, applied via the transumbilical port. The specimen was removed via the vaginal opening after being placed into a retrieval bag. The vaginal opening was then closed laparoscopically via the umbilical portal. The total operative time was 3.7 h with an EBL of 150 mL. The patient was discharged on postoperative day number 1 and resumed normal activity on postoperative day 3. The patient developed a fever requiring readmission and was found to have a fluid collection in the renal fossa that was drained percutaneously without sequelae.

The same group described in detail the work they had done leading up to this procedure, including the use of acute porcine and cadaver models [10]. Three other clinical cases were also attempted prior to this report, but all were ultimately converted to standard laparoscopy. It has been said before that we learn much more from our failures than we do from our success. It seems this was the case for these authors as the lessons learned were elaborated on and used for ultimate success. During the first attempted case, a rectal injury occurred during the insertion of the TriPort. Following this, the authors placed the transvaginal port under laparoscopic visualization. The second case was for an 8-cm upper pole right-sided tumor. This was converted because of failure to progress and highlights the importance of patient selection. During the third attempted case, bleeding was encountered with the suprahilar mobilization. Upon conversion to standard laparoscopy, an unexpected upper pole vessel was identified as the source of the bleeding, which stresses the importance of the use of extra-long instruments and the difficulties encountered when dissecting the upper pole of the kidney via the vagina.

Zorron *et al.* reported their experience with a transvaginal hybrid NOTES renal cyst decortication using a retroperitoneal approach [15]. A 67-year-old female presented with left-flank discomfort and was found to have a 9.5-cm left lower pole simple renal cyst. The patient was placed in the lithotomy position with Trendelenburg and a posterior colpotomy was made. The retroperitoneal space was developed with combined digital and endoscopic dissection. A two-channel videocolonoscope was used to perform the initial portion of the procedure and insufflation was achieved via one of the working channels. The scope was placed directly through the colpotomy and no port was used. During the retroperitoneoscopy, anatomic landmarks were identified, including the psoas muscle, vena cava, aorta, inferior mesenteric artery, and ureter. Gerota's fascia was encountered and opened with a polipectomy snare and the renal cyst was identified. At this point there was significant leakage of the pneumoretroperitoneum secondary to a tear in the peritoneum and two 5-mm laparoscopic ports were placed in the left flank to assist with the remainder of the cyst marsupialization, which was completed without complication. The vaginal entry portal was not closed because it was thought that the retroperitoneal structures would be unlikely to herniate through it. The procedure time was 210 min and there were no intraoperative complications. Postoperatively, the patient developed a small amount of pneumomediastinum that resolved with conservative management. Following the surgery, the patient's flank discomfort resolved and she denied any vaginal discomfort. This is the only clinical report in the urologic literature that attempted to use flexible endoscopes to actually perform the procedure. Most have abandoned these instruments in favor of standard laparoscopic instruments, which can be used with transvaginal surgery and are able to provide much more robust traction.

NOTES

Ultimately, Kaouk *et al.* were able to perform the first human urologic NOTES case without any transabdominal ports. They successfully completed a transvaginal NOTES nephrectomy in a 58-year-old woman who presented with recurrent urinary tract infections and was found to have an atrophic right kidney with 11% function [16]. She was placed in the lithotomy position with the right arm tucked over her chest and a wedge placed

under her right side to place her in a slightly lateral position. The table was then rotated in order to provide additional passive retraction of the colon. A posterior colpotomy was performed and the peritoneal cavity was entered. Initially, a flexible gastroscope was introduced for a diagnostic evaluation and to confirm there were minimal pelvic adhesions. A GelPort was then placed transvaginally with two 10-mm and one 5-mm trocar placed through it. As described with their hybrid NOTES procedure, a 5-mm flexible-tip endoscope was used in conjunction with 45-cm articulating laparoscopic instruments. During the initial reflection of the colon, the downward torque placed on the GelPort resulted in a significant and problematic CO_2 leak that necessitated its exchange with the multichannel TriPort. The procedure progressed as it would for a standard laparoscopic nephrectomy. The ureter was divided with Hem-O-lok clips (Weck Closure Systems, Research Triangle Park, NC, USA). The GelPort was then reinserted and because the kidney was now being retracted laterally, no downward torque was needed, so there was no longer an issue with leakage of the pneumoperitoneum. The renal artery and vein were divided with an endovascular stapler. The remaining superior attachments were divided with an extra-long (65 cm) monopolar hook. The kidney was placed into a retrieval bag and removed via the vaginal incision. The vaginal incision was closed and a vaginal pack was placed. The procedure was completed in 420 min with an estimated blood loss of 50 mL. No transabdominal ports or instruments of any type were used at any point throughout the procedure, which makes this the first report of a "true" human NOTES nephrectomy. The patient was discharged 19 h after surgery and reported no pain on a visual analog pain scale (score 0 of 10).

Other considerations

Patient perspective

NOTES represents a major change in the traditional approach to surgery, so patient acceptance is an important consideration. At present, the transvaginal approach appears to provide the best opportunity for clinical NOTES in urology. Women have been surveyed as to their views and acceptance of a proposed transvaginal procedure. Peterson *et al.* surveyed 100 women to obtain their opinions and define their concerns [17]. The women were given a written description of standard laparoscopic surgery and NOTES, and were then asked to respond to a 10-question survey. Sixty-eight percent indicated if data showed the equivalency of NOTES that they would prefer a transvaginal approach. The reasons given for this decision included cosmetic reasons (61%), to minimize hernia formation (90%), and to minimize pain (93%). Regarding potential complications, concerns included infectious issues (83%), impact on sexual health (81%), and effects on fertility (61%). The women who preferred the NOTES approach were more concerned with cosmesis, hernia formation, and pain. Those who did not want a transvaginal procedure were most concerned with infectious issues.

Another survey of 300 women was reported by Strickland *et al.* [18]. This questionnaire also focused on their opinion regarding NOTES versus standard laparoscopic surgery. Interestingly, 66% of this group of Australian women indicated they did not dislike scars after a surgical procedure. Not surprisingly, this feeling was less prevalent in younger women. Most women (72%) indicated they would be neutral or unhappy with the prospect of NOTES. When asked which type of procedure they would prefer, 65% indicated they would prefer standard laparoscopic surgery.

These and other surveys indicate that while there is public interest in NOTES, the procedure-related risks, pain, and recovery time seem to be the most important priorities for patients [19].

Multidisciplinary team

Many of the quantum leaps in surgery have resulted from the collaborative efforts of physicians across disciplines, as was the case with the first laparoscopic nephrectomy. It is this collaboration that often allows for the most creative solutions to problems encountered, as each member has a unique perspective to share. Many of the initial reports of the clinical application of NOTES in urology have benefitted from this collaboration with gynecology and general surgery colleagues.

Institutional Review Board

NOTES is still an experimental technique that must only be performed with the upmost emphasis on patient safety. The often spoken dictum of "first do no harm" certainly applies here. NOTES is very early in its development and the available instrumentation and technology are lagging far behind the ideas that have been conceptualized. As with all innovation, the introduction of a new procedure or surgical approach must be cautious so that patient harm is minimized. At least in theory, NOTES seems to represent a potential paradigm shift in surgery, similar to the way laparoscopy forever changed the surgical landscape more than 20 years ago. It is this great potential that makes its introduction into clinical practice even more challenging. As with any new procedure with an unproven feasibility or safety

record, IRB approval is mandated prior to performing NOTES clinically.

Relationship of LESS and NOTES

The development of laparoendoscopic single-site surgery (LESS) and NOTES will likely prove to be mutually beneficial in the future progress of both of these techniques. In fact, in urology it seems this is already the case to some extent. The recent interest in urologic NOTES has lead to the rapid realization that the available endoscopic instrumentation is woefully inadequate for the majority of urologic intra-abdominal procedures. Almost simultaneous to the introduction of NOTES, there has been an explosion in the interest in LESS. The clinical experience with LESS is now quite extensive and the rapid assimilation of LESS is likely due to its similarity with standard laparoscopic surgery in terms of technique and instrumentation. As experience with LESS has grown, it became apparent that this technique and instrumentation could be used for NOTES, particularly if performed via a transvaginal approach, which would allow for the use of rigid instruments. Most of the reported clinical NOTES cases have used the same ports and instruments that are commonly used with LESS. It appears the experience with LESS facilitated the clinical introduction of NOTES in urology. It is likely that this relationship will continue to prosper as new purpose-built instrumentation is developed. A small flexible robotic platform can certainly be imagined that could be inserted through a small abdominal incision to perform LESS and, eventually, through a natural orifice to perform NOTES.

Clinical role in urology

NOTES is an experimental technique that is in its infancy. While a human transvaginal NOTES nephrectomy has now been successfully achieved, the ultimate role NOTES will have in urology is unclear. This will depend on multiple factors that include patient acceptance, instrument development, and a proven feasibility and safety record. Regardless of the final fate of NOTES in urology, physicians and patients are sure to benefit. The recent interest in NOTES will hopefully push industry to develop better and novel instrumentation. While NOTES is certainly deserving of additional investigation, the ultimate role it may play in the management of urologic disease remains to be determined.

Conclusions

The clinical use of NOTES in urology has been extremely limited to date largely due to the well-recognized lack of appropriate instrumentation. Human ingenuity will eventually meet the technical challenges currently found with the available instrumentation. Continuing the innovative efforts to modify and improve existing surgical equipment and technology will no doubt benefit future patients, regardless of the approach.

CHAPTER 106

Laparoendoscopic Single-Site Surgery: Ports, Access, and Instrumentation

Michael A. White & Jihad H. Kaouk
Glickman Urological and Kidney Institute, Cleveland Clinic, Cleveland, OH, USA

Introduction

The prevalent implementation of laparoscopy has introduced a new era in surgery. Lately there has been a push to further reduce the invasiveness of laparoscopic surgery. To facilitate this goal, surgeons have proposed limiting the number of abdominal incisions with laparoendoscopic single-site surgery (LESS) or eliminating them completely through natural orifice translumenal endoscopic surgery (NOTES) [1]. The latter has been demonstrated primarily in preclinical animal models with limited experience amassed in clinical series; as such, the human experience with this technique is still experimental [2–6]. Conversely, LESS has undergone laboratory and clinical work and has proven to be feasible and applicable to humans [7–12].

LESS is not new and has been documented in the literature since 1997 for various specialties, including general surgery and gynecology [13, 14]. Widespread acceptance of this technique did not occur due to the limitations experienced with the current technology available at that time. Current innovations such as articulating instrumentation and novel multilumen ports have fostered a renaissance for LESS with several recent clinical series reporting successful completion of a range of procedures [8–12]. The proposed benefits of LESS include improved cosmesis and reduced postoperative pain.

Over a relatively short period of time, LESS has undergone an evolution including updates in port, instrument, and scope design. Initially, LESS was performed through a single incision with multiple trocars placed through separate fascial stabs, but in an attempt to reduce fascial trauma, multichannel laparoscopic ports were developed. An effort to overcome clashing and lack of instrument triangulation, experienced with straight laparoscopic equipment, has led to the development of prebent, flexible, and articulating instruments. Finally, advances in optical technology have allowed for smaller diameter lenses, improved resolution, ability to deflect, and lower profile built-in cameras.

Special technical considerations

Transperitoneal LESS procedures

Transperitoneal LESS procedures may require adjustments regarding instrumentation and positioning. Longer instruments may be necessary, especially with larger patients and during adrenalectomy, to account for the low placement of the port through the umbilicus. Articulating instruments may also be the equipment of choice due to the large operating space and the need to access all angles of the operative field. It is also more likely that a longer telescope with a flexible tip is needed to visualize target organs.

Retroperitoneal LESS Procedures

The retroperitoneum is a smaller space and is therefore more prone to instrument crowding and clashing. Shallower ports are often better to use as they function-

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

ally increase the operative field. Use of flexible or bent instruments may minimize clashing of instruments.

Obese patients

There are several technical caveats that may be useful when performing LESS urologic procedures in obese patients. More of a full-flank (90°) position is required in obese patients versus a semi-flank position (45–60°) for the nonobese during upper tract procedures. This allows for displacement of the pannus away from the surgical field and further helps displace bowel medially. The bony anatomic landmarks, including the anterior iliac spine and pubic symphysis, are critical to maintain midline orientation. This is especially important for the patient with a pendulous pannus that shifts the umbilicus significantly towards the pubis. While the access site for transperitoneal procedures is typically placed in the umbilicus, the patient's abdomen is either lifted with padding or fixed with 3-inch cloth tape so that the umbilicus is lifted into a more anatomic position prior to starting surgery. Additionally, longer instruments may be necessary and a higher insufflation pressure needed to account for the added weight of the abdominal wall.

Ports

In its truest form LESS represents laparoscopic surgery performed through a miniaturized incision at a single site. Even though these procedures are commonly performed via a commercially made single port, the term "single port" is avoided because these procedures can be performed through a small incision with multiple trocars. Additionally, standard trocars can be added adjacent to the commercially available "multichannel ports," through the same skin incision but into a separate fascial stab in a hybrid format. This is particularly helpful during robotic LESS (R-LESS). There are several single port devices available, each with their own advantages and disadvantages (Table 106.1).

Multiple trocar configuration

This trocar configuration consists of a single skin incision with several ports placed through separate fascial sites. The cannulas are bunched together with contact between the external housings. Piskun *et al.* were the first to report utilizing multiple trocars through a single transumbilical incision to perform a cholecystectomy [13]. Two separate 5-mm trocars were placed through an intraumbilical incision via two separate fascial stab incisions. The procedure was performed and the specimen extracted after the fasciotomies were joined, leaving a near scar-free appearance. Raman *et al*. subsequently used multiple trocars through a single incision with three separate fascial stab incisions for urologic purposes. They were able to complete two of three nephrectomies without adding additional trocars and found "the single trocar to be more cumbersome with fewer degrees of freedom than three adjacent trocars" [7]. The multiple trocar configuration can be performed with traditional 5-mm trocars or specifically designed kits.

AnchorPort™

The AnchorPort (Surgiquest, Orange, CT, USA) was created in an effort to reduce external cannulas clashing (due to bulky 5-mm external cannula housings) and improve range of motion. AnchorPort's small and low-profile housing allows cannulas to be placed close together (Figure 106.1A). Additionally, the ports contain an internal anchor which prevents them from dislodging. Lastly, optical entry can be used on all entries, not just the first.

Multichannel laparoscopic ports

The multichannel laparoscopic port is placed through a single skin and fascial incision. The ports are placed via an open (Hasson) technique, primarily through the umbilicus.

R-Port/Triport/Quadport

The TriPort and QuadPort (Advanced Surgical Concepts, Wicklow, Ireland) represent an evolution of the R-Port and have been used extensively in LESS [8, 10, 12, 15–24]. They differ in the number of available operative inlets and overall size, but otherwise are identical. The devices consist of a retractor and valve. The retractor consists of one internal ring and two external rings, and a double-over cylindrical plastic sleeve; the latter is attached to the inner ring of the two external rings and descends, circles the inner ring, and exits between the two outer rings. The valve component incorporates three or four inlets for introduction of instruments. The three-inlet valve (TriPort) has one inlet for a 12-mm instrument and two for 5-mm instruments. The larger version (QuadPort) has two inlets for 12-mm and two inlets for 5-mm instruments (Figure 106.1B).

SILS™ port

The SILS port (Covidien, Cupertino, CA, USA) is a new introduction to the field of LESS. The SILS port is a flexible laparoscopic multichannel port that can accommodate up to three instruments through a single incision. It is made of soft foam that is designed to conform to

Table 106.1 Available single port devices.

Access device	Features	Advantages	Disadvantages
TriPort (Olympus)	Flexible multichannel valve; up to three instruments (1 × 12 mm; 2 × 5 mm); covered with an elastomer	Adapts to incision and abdominal wall thickness	Fragile when using 12-mm Instruments Lubrication required Constrictive outer ring Gas leakage
Quadport (Olympus)	Flexible multichannel valve; up to four usable instruments (1 × 15 mm, 1 × 10 mm, 2 × 5 mm); covered with an elastomer	Adapts to incision and abdominal wall thickness	Fragile when using 12-mm instruments Lubrication required Constrictive outer ring Gas leakage
SILS port (Covidien)	Flexible platform; up to three individual ports and instruments	Easy exchange of different size ports	Difficult to use with large abdominal wall
GelPoint (Applied Medical)	Three components: GelSeal™ providing PseudoAbdomen™ platform; Alexis™ wound retractor; self-retaining trocars	Larger outer working profile for enhanced triangulation Adapts to incision and abdominal wall thickness	Fragile Gas leakage during prolonged procedures
AirSeal (Surgiquest)	Oval valveless cannula with invisible pressure seal	Stable CO_2 pressure Multiple instrument insertion	Rigid; less freedom of movement Noisy
AnchorPort (Surgiquest)	Low-profile ports of various lengths placed in close proximity	Anchoring system Optical entry	Rigid; less freedom of movement
Homemade	Alexis™ wound Retractor, Latex glove, variable ports	Inexpensive Larger outer working profile for enhanced triangulation Adapts to incision and abdominal wall thickness	Must be built for each case
Octo-port (Dalim SurgNET)	Wound retractor, three flexible caps, three cannulas, two channels for insufflation and smoke evacuation	Adapts to incision and abdominal wall thickness Multiple caps allow for tailoring of procedure	Fragile when using 12-mm Instruments Lubrication required Constrictive outer ring Gas leakage
SSL Access System (Ethicon Endo-Surgery)	Wound retractor, 360° rotation of the seal cap, three entry points, insufflation channel	Quick reorientation of instruments during procedures, reduced need for instrument exchanges	Rigid; less freedom of movement
X-CONE (Karl Storz)	Two-piece design, flexible cap, three cannulas	Reusable Easy to place	Gas leakage from cap Two pieces disengage

the contours of the incision. It contains a built-in insufflation valve and three port sites that can accommodate two 5-mm cannulas and a single 12-mm cannula (Figure 106.1C). The SILS port has been reported for various surgeries [25–27].

GelPort™/GelPoint™/Alexis™

The GelPort laparoscopic system (Applied Medical, Rancho Santa Margarita, CA, USA) combines a GelSeal cap with the Alexis wound retractor. The GelSeal cap attaches to the wound retractor by means of a latch. Designed for hand-assisted laparoscopic procedures, the GelPort has been used during LESS and R-LESS procedures [27–29]. Multiple trocars of varying size can be introduced through the GelSeal cap and the specimen can be extracted once the GelSeal cap has been removed.

The GelPoint represents the evolution of the GelPort™ and is designed specifically for LESS (Figure 106.1D). It has a smaller gel cap and four premade self-retaining 5-mm trocars, though various sized trocars can be placed similar to the GelPort. Additionally, there is an insufflation port built into the side of the device and the Alexis wound retractor is fitted with a tether for easier removal.

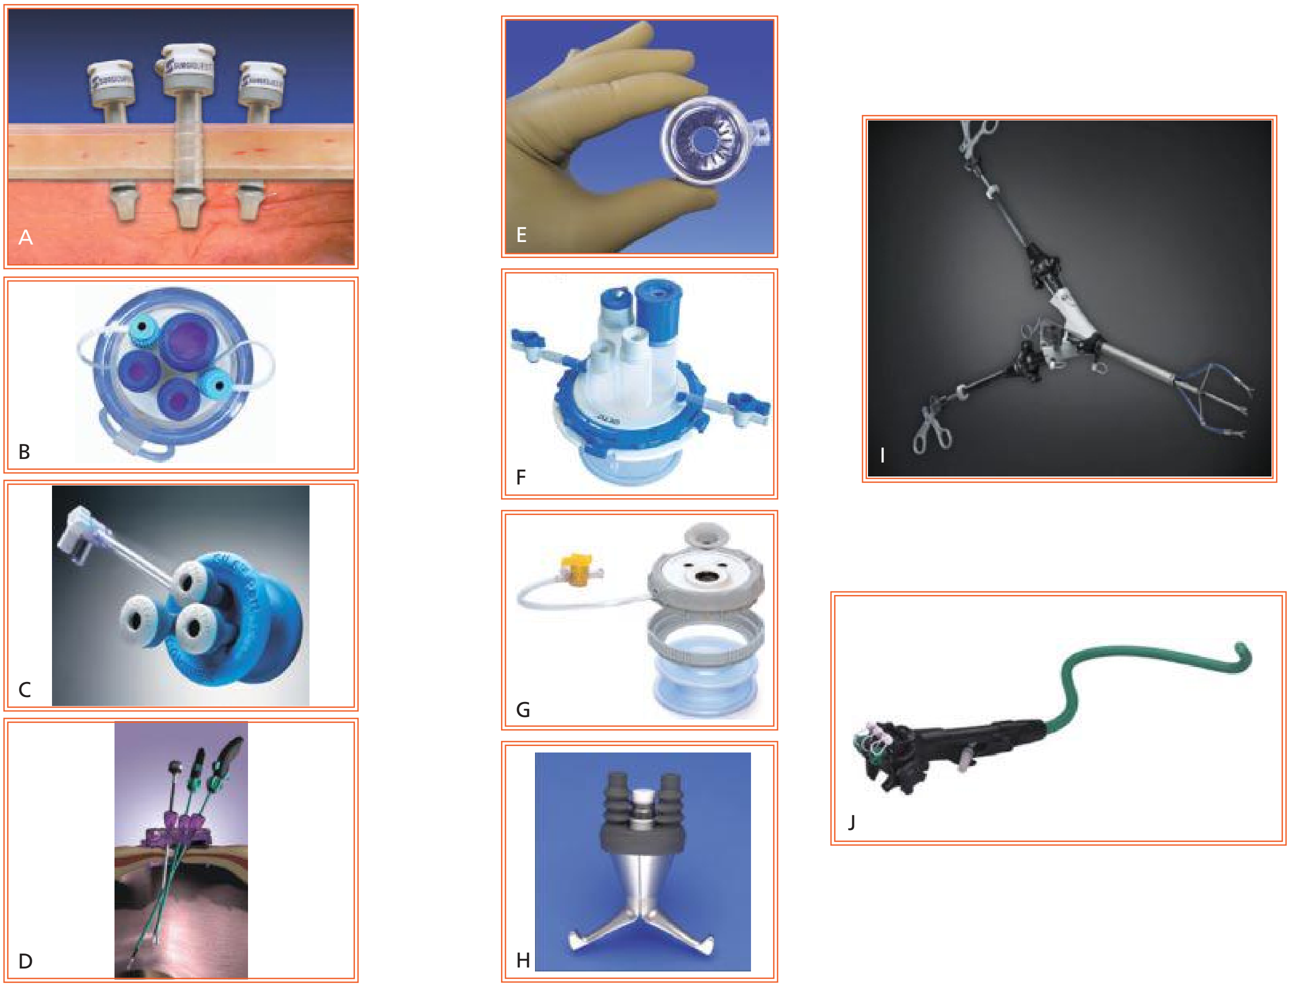

Figure 106.1 Commercially available multichannel laparoscopic ports. AirSeal™

AirSeal (Surgiquest) is a technology which recirculates and filters peritoneal gas. It removes smoke from the field of vision and filters it, instead of venting it into the room. There are no valves or gaskets required, so multiple instruments and a camera can be inserted without a reduction in pneumoperitoneum. It consists of a single port with a rigid external housing and an oval cannula (Figure 106.1E). The system monitors and allows the insufflator to adjust as needed to ensure a stable pneumoperitoneum.

Octo-Port™

The Octo-Port (Dalim SurgNET, Seoul, South Korea) consists of a self-retractor that retracts the abdominal wall and protects the incision. The retractor varies in size from 1 to 5 cm. Three caps are available that attach and provide a different array of cannulas. The large caps contain two separate channels that allow for insufflation and smoke evacuation. Two configurations are available for single-site surgery: a cap with two 10/12-mm cannulas and a single 5-mm cannula; and a cap with one 10/12-mm cannula and two 5-mm cannulas. The cannulas are different heights to prevent external clashing and the cap is flexible to allow for an improved range of motion (Figure 106.1F).

Ethicon Endo-Surgery SSL Access System

The SSL Access System (Ethicon Endo-Surgery Inc, Cincinnati, OH, USA) is a single-port access device that consists of a wound retractor and a cap that attaches via an attachment ring. The cap has two 5-mm seals and a larger 15-mm seal in a low profile design. An additional

channel found on the cap allows for insufflation. The integrated seal system does not require trocar use, possibly eliminating interference of trocar cannulas in the abdominal cavity. Unique to the device is the 360° rotation of the seal cap, which enables quick reorientation of instruments during procedures and reduces the need for instrument exchanges (Figure 106.1G).

X-CONE

The X-CONE (Karl Storz Endoscopy America, El Segundo, CA, USA) is a reusable access device for transumbilical laparoscopy. It consists of three working channels that permit the introduction of instruments of up to 12.5 mm in size. A plastic, but flexible, cap with three entry sites attaches to the two-piece metal device. Special curved instruments are encouraged with this device in addition to an extra-long endoscope. It is introduced via a Hasson technique in two pieces that then snap together (Figure 106.1H).

Homemade single-port device

Commercially produced single ports are not universally available and have pushed surgeons to create their own access devices [30–33]. These access devices consist of the Alexis wound retractor, a sterile surgical glove, and standard laparoscopic ports (Figure 106.2). The size 7 surgical glove is attached to the wound retractor and three to four of the finger tips are removed so the cannulas can be inserted and tied in place. Insufflation is performed through the previously placed ports.

Multichannel hybrid laparoscopic ports

The multichannel hybrid laparoscopic port is a complete system that behaves more as a surgical platform than just a port. The multichannel hybrid laparoscopic ports require specialized instruments (flexible gastroscope, etc.) and have been conceived as much from NOTES as they have from LESS. These ports are placed through a single skin and fascial incision using the Hasson technique.

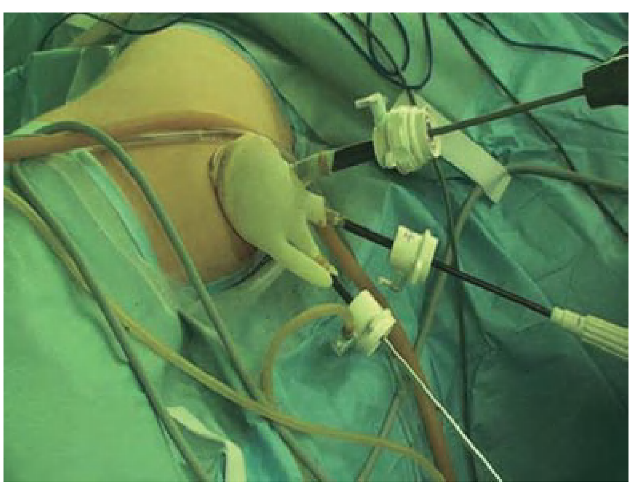

Figure 106.2 Homemade multichannel laparoscopic port.

SPIDER™

The SPIDER Surgical Platform (Trans Enterix Inc, Durham, NC, USA) is a single-port access device that requires special instrumentation to perform LESS. It is available in two models and consists of an insertion trocar that guides the distal end into the abdominal cavity and four working channels (Figure 106.1I). Two flexible channels, known as IDTs (instrument delivery tubes), facilitate motion to allow for a multidirectional and triangulated approach within the surgical field. The flexible IDTs are guided by a gimbal system at the proximal end, which provides 360 degrees of freedom at the distal tips. Crossing of instruments is not necessary and therefore the left hand controls the left instrument and the right hand the right instruments. Two rigid channels positioned vertically to the operative field accommodate the use of a scope and any other rigid surgical instrument. Three pneumoperitoneum/vacuum ports exist to maintain pneumoperitoneum and facilitate insufflation and/or smoke evacuation. There is a docking ball that attaches the SPIDER device to the stabilizer. The stabilizer must be purchased separately and attaches to the operating table.

TransPort™

The TransPort (USGI Medical, San Clemente, CA, USA) provides stable access to the operating site via one of the body's natural orifices or an incision in the umbilicus. The TransPort is more akin to a gastroscope/colonoscope than a standard laparoscopic instrument. It has four large working channels, one for an endoscope and three others for large diameter instruments (Figure 106.1J.). This device creates the multitasking platform and utilizes a flexible endoscope along with multiple flexible endoscopic instruments.

Laparoscopic access

Transumbilical

Transumbilical access is the standard for LESS procedures. The umbilicus affords direct entry into the peritoneal cavity and readily hides the surgical scar. Various incisions can be used, including intra-, infra-, supra-, and peri-umbilical. The incision length is chosen based on the minimum amount of space needed to accommo-

date the desired port or trocar configuration. The incision is made through the skin and dermis and carried down to the rectus fascia. For the multiple trocar configuration, the fascia is grasped, elevated, and pneumoperitoneum is achieved with the Veress needle technique. The chosen trocars are then inserted into the abdomen. The AnchorPort system is inserted in a similar fashion, yet optical entry (placement of a 5-mm scope and camera through the port) can be used on all entries, not just the first. The AirSeal single port is inserted in a comparable fashion to a standard optically placed trocar except that a specially designed hand piece allows for an off-set hand position to help guide the cannula.

The TriPort and QuadPort require that a series of manufacturer directions are followed to enable accurate placement. This system can be placed in a closed Veress needle fashion, with an enlarged fascial incision, or with the open Hasson technique. First, the distal ring is loaded into the introducer. The introducer then bluntly dissects through the abdomen. Once through the peritoneum, the thumb-switch on the introducer is depressed and the distal ring is deployed. The introducer is then removed and the sleeve is pulled upwards to bring the internal ring into contact with the inner abdominal wall. The outer ring is then pushed down to create further retraction. The excess sleeve is removed and slack in the port is removed with the retracting ribbon. Insufflation is attached to the appropriate cannula to create pneumoperitoneum.

The SILS port, GelPort/GelPoint, Octo-Port, SSL Access device, X-CONE, and the handmade device are inserted into the abdomen in a similar fashion. After the umbilicus has been dissected free of the rectus fascia, and the preperitoneal fat visualized, entry into the abdomen is gained bluntly with either a finger or hand-held clamp. The incision in the fascia is then enlarged by at least 1.7 cm up to 7 cm. The Alexis wound retractor is inserted through the fascia and care is taken to avoid entrapping bowel when folding the retractor. Both the gel cap of the GelPort/GelPoint or surgical glove of the handmade port is fixed into place and insufflation is begun through the attached cannula or a preinserted laparoscopic trocar. The fascial incision for the SILS port should be no larger than 2 cm to create a good seal and maintenance of pneumoperitoneum. The flexible SILS port is folded at its lower edge (contralateral to the insufflation system), and with the use of a proper surgical instrument (i.e. Péan clamp) is advanced under direct vision into the abdomen.

Extraumbilical transperitoneal

Though transumbilical access is the most common site for LESS, extraumbilical incisions have been utilized, including flank, paramedian, Pfannenstiel, and suprapubic [8, 11, 21, 29, 34]. By off-setting the incision closer to the intended target organ, a more direct access to the surgical field is created, which may improve tissue retraction and instrument range of motion; however, the scar may be more visible outside the umbilicus.

Retroperitoneal

Retroperitoneal access is achieved with an open (Hasson) technique. A 1.5-cm transverse skin incision is made at or just below the tip of the 12th rib. The flank muscle fibers are separated with two S-retractors to visualize the anterior thoracolumbar fascia, which is incised to enter the retroperitoneal space with the tip of the index finger. Digital dissection is performed along the anterior surface of the psoas muscle and fascia, posterior to Gerota's fascia (to create a space for the balloon dilator). A PDB balloon dilator (US Surgical, Norwalk, CT, USA) is inserted into the retroperitoneum and approximately 600 mL of air is instilled in the balloon to create the retroperitoneal space. This maneuver ensures that the peritoneal deflection is mobilized medially. In this manner, the *en bloc* kidney and surrounding Gerota's fascia are mobilized medially, thus exposing the posterior aspect of the renal hilum and the adjacent vessels to clear laparoscopic view. Once access has been gained, the single port of choice is utilized. Both the TriPort and the homemade single port have been successfully used in retroperitoneal LESS [24, 31].

Laparoscopic instrumentation

During LESS, instruments are placed in parallel, resulting in significant instrument clashing. To minimize clashing, specifically designed instruments have been created, including instruments that are prebent and ones that articulate. Additionally, improvement in available optics in the form of smaller diameter scopes, high-definition imaging, low-profile attached cameras, and deflectable scope tips significantly contribute to the wider acceptance of this surgical technique.

Prebent instruments

Prebent instruments (Olympus, Hamburg, Germany; Karl Storz, Tuttlingen, Germany) are designed to improve ergonomics and reduce external crowding of instrumentation around the access site (Figure 106.3A). Compared to standard laparoscopic instruments, they allow for the ability to triangulate and reduce internal and external clashing. When compared to flexible instrumentation in the laboratory setting, prebent instruments were less time-consuming and were found to have better maneuverability [35].

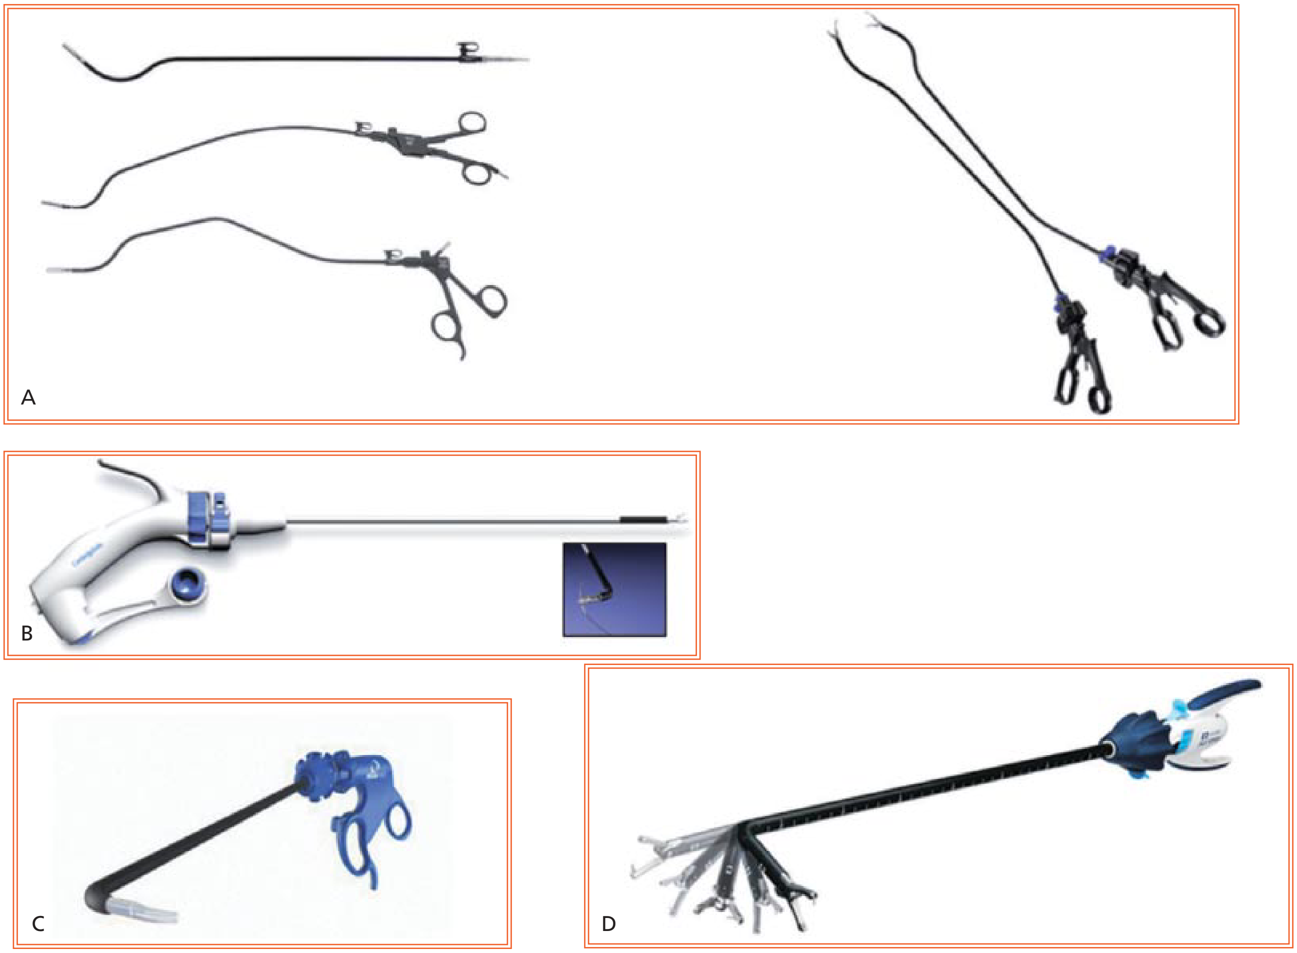

Figure 106.3 Commercially available laparoscopic instrumentation: (A) prebent instruments, (B) Autonomy Laparo-Angle, (C) Real Hand, (D) Roticulator.

Flexible instruments

Autonomy Laparo-Angle™

The Autonomy Laparo-Angle (Cambridge Endo, Framingham, MA, USA) series consists of Metzenbaum scissors, a Maryland dissector, monopolar hook cautery, and needle holders. The system allows for 7 degrees of freedom, full articulation, a tip that can rotate 360° around its axis, the capability of performing simultaneous actions such as articulating downward while rotating, and a handle that locks at any angle and rotates (Figure 106.3B).

Real Hand™

Real Hand instruments (Novare Surgical Systems, Cupertino, CA, USA) were designed with an EndoLink® mechanism which affords 7 degrees of freedom of movement. The full line of instruments includes a bipolar coagulator, various graspers, dissectors, and needle drivers. All have a locking mechanism, which allows for use as a straight or up to 90° angulated instrument (Figure 106.3C).

Roticulator™ articulating instruments

The Roticulator line of instruments (Covidien, Cupertino, CA, USA) include a grasper, shears, and dissector. The Roticulator offers 0–80° of articulation, 360° of rotation at all articulation angles, and spin-lock rotation position lock, and can perform as a fully rigid straight instrument and is 5 mm in diameter (Figure 106.3D).

Optics

Advances in the available optical systems in laparoscopy has greatly the facilitated the progression of LESS. From 5-mm lenses to articulating scopes, the field of fiberoptics is largely responsible for the re-emergence of LESS (Figure 106.4).

Figure 106.4 Laparoscopic optics. (A) Endochameleon, (B) IDEAL EYES (courtesy of Stryker), (C) EndoEYE LTF, (D) EndoEYE LS.

Endochalmeleon and extra-long HOPKINS®

The Endochameleon (Karl Storz, Tuttlingen, Germany) is a 10-mm laparoscope that allows the user to adjust the viewing direction between 0° and 120° as the surgical field requires. As a result, intraoperative telescope changes are often unnecessary, and the surgeon is able to optimally view the entire surgical field. The extra-long 5-mm HOPKINS endoscope (Karl Storz, Tuttlingen, Germany) has a working length of 50 cm to combat external collisions encountered during LESS (Figure 106.4A).

IDEAL EYES

The IDEAL EYES HD articulating 10-mm laparoscope (Stryker, Kalamazoo, MI, USA) includes distal flexible-tip technology to allow for 100° of flexion in all directions. This scope transmits both HD (1280 × 1024) and HDTV (720 pixels) video signals for optimal viewing in all areas of surgery. The IDEAL EYES is also available in a 5- and 10-mm non-HD format. The scope is 45 cm in length and was designed for bariatric surgery, but its length mean that external collisions are avoided during LESS (Figure 106.4B).

EndoEYE

EndoEYE technology (Olympus Surgical, Center Valley, PA, USA) integrates a distally mounted camera chip inside the laparoscope along with the light-guide cable to deliver a lightweight all-in-one system. Elimination of an externally mounted camera decreases external collisions. The rigid scopes are available in 5 and 10 mm versions with 0°, 30°, or 45° direction of views. The EndoEYE LTF includes all of the features of the previous mentioned laparoscopes with the addition of a flexible tip. A 100° field of view from multiple angles can capture the desired location head-on, from above, or even from behind. The flexible tip eliminates the need to change between 0° and 30° scopes intraoperatively (Figure 106.4C). The EndoEYE LS is a 5-mm 30° digital scope that allows the control section of the system to be bent by as much as 90°, further reducing the profile and limiting external instrument crowding (Figure 106.4D.).

Conclusions

LESS is developing at a rapid pace and as more surgeons adopt this laparoscopic approach, further refinement in technology will be identified. Although no perfect dedicated LESS ports exist, significant improvement in the LESS toolbox allows the LESS approach to spread significantly. Computer interface or robotic surgical instruments will better assist surgeons to further minimize access site morbidities.

CHAPTER 107

Laparoendoscopic Single-Site Upper Tract Surgery

Soroush Rais-Bahrami,[1] Abhay Rane[2] & Lee Richstone[1]

[1]The Arthur Smith Institute for Urology, Hofstra North Shore–LIJ School of Medicine at Hofstra University, Lake Success, NY, USA

[2]East Surrey Hospital, Redhill, Surrey, UK

Introduction

Since 1991, when the first laparoscopic nephrectomy was reported, laparoscopy has flourished in urology for the treatment of both benign and malignant conditions. Techniques and instrumentation have evolved to address more complex cases and pathology. New trocars, optics, instruments, and robotic devices have all been developed in a collective effort to improve efficacy, minimize patient morbidity, and reach for superior cosmetic results.

Laparoendoscopic single-site (LESS) surgery is one example of how new technology and new techniques have converged to allow for the performance of complex surgery through fewer incisions. In a short time span, nearly the entire gamut of urologic procedures has been performed via a LESS approach [1, 2]. Moreover, the diffusion of LESS has been fairly rapid across the globe. The goal of LESS surgery is to provide equivalent surgical outcomes with improved cosmetic results. Ongoing research is aimed at clarifying what, if any, perioperative or convalescence-related benefits may be offered by minimizing the number of incisions and cumulative incision length used compared to conventional laparoscopy [3].

Of the cases reported in the literature to date, the largest experience of urologic LESS surgery has been in the upper urinary tract, specifically renal procedures [1]. Upper tract urologic LESS surgery consists of both extirpative and reconstructive procedures of the kidneys, adrenal glands, and ureters. The anticipated surgical volume of LESS procedures for nearly all renal and adrenal pathology is expected to be intermediate or high in volume [4].

Although LESS surgery is a direct and natural extension of multiport, or "conventional," laparoscopy, there are several unique aspects to LESS. Access is most commonly through the umbilicus as the "single site," however, other locations can be utilized, such as a suprapubic or "mini-Pfannensteil" approach, a transabdominal or retroperitoneal flank approach, or even a Gibson incision–retroperitoneal approach [5–7]. Access can be via a specialized port, or clustered conventional ports, as discussed in Chapter 106. A wide variety of purpose-built instrumentation and various options for imaging (e.g. rigid vs flexible endoscopy) are available, and also discussed in Chapter 106. For each LESS operation, although modifications in technique and maneuvers are often made, conventional laparoscopic techniques are largely followed. As our overall experience with LESS surgery continues to grow and more urologists become familiar with the associated technology, we expect LESS to be adopted into everyday clinical practice of the future. It is certain that advances in technology and in particular robotics will allow single-site access to be commonplace with expanding indications and outcomes data to support its use. This chapter will discuss these interesting facets of urologic LESS surgery of the upper tract.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Trocar/port-site placement

Umbilical and periumbilical

The majority of urologic upper tract LESS surgery is approached via an umbilical single-site access. Published reports of LESS have used all of the wide variety of access modalities available, both commercially manufactured and "homemade" designs created by surgeons using already available devices [1, 5, 8, 9] (Table 107.1) The umbilical trocar site is most often employed as it provides the opportunity to conceal incisions/scars. Mulitport trocars, GelPort™/GelPoint™ devices (Applied Medical, Rancho Santa Margarita, CA, USA), or a clustered series of low-profile trocars can be employed within the umbilicus. Multiport trocar placement at the umbilicus requires a single incision at the umbilicus, ranging from 2–5 cm to accommodate the chosen trocar (Figure 107.1). Use of separate low-profile trocars allows for more independent mobility and use of reusable devices, also using an incision ranging from 2–3 cm at the umbilicus (Figure 107.2).

Compared with conventional laparoscopy, during LESS surgery the laparoscope and working instruments

Table 107.1 LESS access modalities.

Device	Features
R-Port (Advanced Surgical Concepts, Dublin, Ireland)	
TriPort	Two 5-mm ports, one 12-mm port, one insufflation channel
	Incision required: 1.0–2.5 cm
	Disposable
QuadPort	Two configurations: (1) four 12-mm ports, one insufflation channel; (2) two 12-mm ports, one 5-mm port, and one 15-mm port, one insufflation channel
	Incision required: 2.5–60 cm
	Disposable
Uni-X (Pnavel Systems, Brooklyn, NY, USA)	Three 5-mm ports, one insufflation channel
	Incision required: 2 cm
	Disposable
UNO (Ethicon Endo-Surgery, Cincinnati, OH, USA)	Two 5-mm ports, one 15-mm port with 5-mm reducer cap
	Incision required: 1.5 cm
	Disposable
X-Cone (Storz, Tuttlingen, Germany)	Four 5-mm ports, one 5–13-mm port
	Incision required: 2.5–3 cm
	Reusable with up to 20 sterilizations
GelPort/GelPoint (Applied Medical, Rancho Santa Margarita, CA, USA)	Accepts multiple conventional trocars or direct insertion of
	instruments
	Incision required: 1.5–7 cm
	Disposable
SILS Access (Covidien, Hamilton HM FX, Bermuda)	Three foam insertion sites for passage of low-profile trocars
	Incision required: 2.5–3 cm
	Disposable
AirSeal (Surgiquest, Orange, CT, USA)	Uses recirculating CO_2 to create seal, may pass multiple instruments through ports of varying calibers
	Incision required: 1.5–2.5 cm
	Disposable

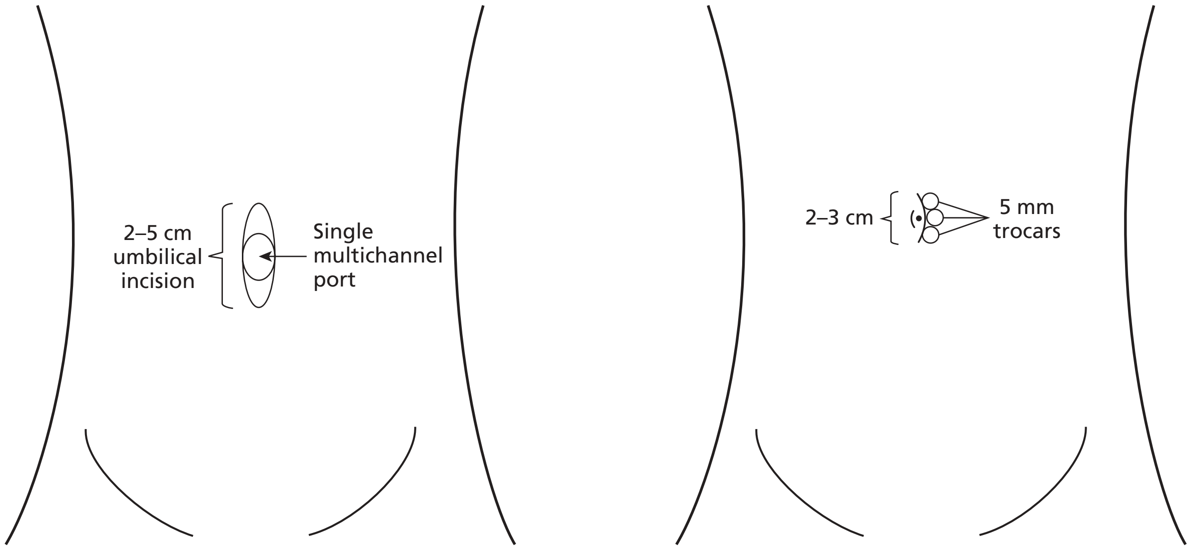

Figure 107.1 Insertion of a multiport trocar at the umbilicus.

Figure 107.2 (A) Insertion of three 5-mm low-profile trocars through a small umbilical incision. (B) Postoperative scars demonstrating positioning and proximity of trocars to the umbilicus.

are in much closer proximity to one another due to the nature of single-site access. This can necessitate the use of flexible scopes and/or instruments to avoid clashing and to allow for triangulation. The umbilical port site allows for adequate access to the upper tract urologic organs with the use of regular length instrumentation, in most cases.

When treating obese patients, lateralization of the centrally located single incision may be warranted toward the side of intended surgery. The surgeon must consider whether this lateralized incision, no longer "hidden" within the umbilicus, still offers potential cosmetic advantages to the patient on a case-by-case basis. Alternatively, a retroperitoneoscopic LESS approach can be employed. Lateralization of the single site of access is akin to the lateralization of trocars employed during conventional laparoscopy in this patient population. Typically this maintains the midpoint of the incision at the craniocaudal level of the umbilicus, but simply shifts it laterally toward the targeted kidney or adrenal gland, providing improved visualization with the laparoscope and simpler reach with the working instruments. Considerations when employing this modification in trocar placement include: the risk of developing incisional hernias, anatomic approach to traversing versus splitting muscle layers, as well as postoperative pain and cosmesis.

Suprapubic or "mini-Pfannenstiel" approach

A suprapubic approach has been reported for LESS simple, radical, and donor nephrectomy, as well as LESS nephroureterectomy. In selected patients, a cosmetic advantage may be obtained by concealing the single incision below the waistline. A small, or "mini-Pfannenstiel," incision is employed that ranges between 5 and 8 cm in size. The size of the incision should allow for specimen extraction, but be as small as possible to optimize cosmesis. Access can be gained with either a multiport device (Figure 107.3) or using independently inserted, low-profile trocars [6, 10–12].

The suprapubic approach has more theoretical advantage in cases that require a sizable incision for specimen extraction, such as simple, radical or donor nephrectomy or nephroureterectomy, in contrast to purely reconstructive surgery (e.g. LESS pyeloplasty) or surgery requiring extraction of small specimens (e.g. LESS cyst decortication or LESS partial nephrectomy). To allow for

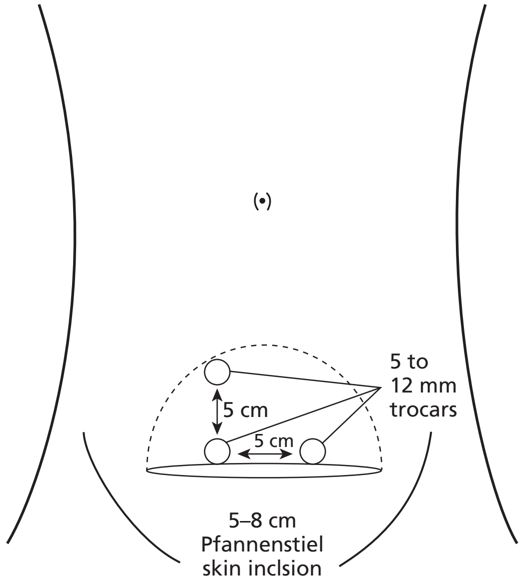

Figure 107.3 Insertion of three 5-mm low-profile trocars through a Pfannenstiel incision.

full access and ability to dissect circumferentially around the upper pole and posterolateral attachments of the kidney, it is useful to have bariatric and articulating laparoscopic instruments available.

Use of accessory and needlescopic trocars

Although even complex reconstructive LESS procedures, such as pyeloplasty and partial nephrectomy, can be performed with no accessory points of entry [6], the use of accessory trocars or 1.9-mm needlescopic instruments has been reported extensively in the early experience of LESS. These added instruments act as an adjunct to the single-site approach and provide for instrument triangulation and added retraction, or can assist with intracorporeal suturing and knot tying. Accessory ports create a bridge between conventional laparoscopy and LESS as surgeons learn LESS surgery, and play a critical role in challenging cases in which triangulation for adequate retraction and dissection is not adequately achieved with single-site access and available instrumentation.

With minimal to no morbidity, needlescopic instruments have been reported to enhance surgeon confidence and ensure patient safety during the diffusion of this new and challenging technique [4]. As experience with LESS increases and surgeons progress along the learning curve, the use of accessory trocars for assistance in triangulation and retraction will likely decrease. However, there will likely always remain an important role for accessory trocars or needlescopic instruments for more complex surgical cases. Moreover, additional access is always preferable to any compromise in safety or efficacy. Accessory trocars measuring from 5 to 12 mm in diameter have been reported. These are used by some urologists during LESS donor nephrectomy to allow for the expeditious and safe maneuvers necessary to limit the warm ischemia time of the renal allograft specimens. They also are adjuncts to LESS for complex reconstructive procedures or in patients with anatomic challenges requiring extensive adhesiolysis or body habitus limiting instrument flexibility. The site of accessory trocar placement can also be used as the location for drain placement at the culmination of the case.

Extirpative surgery

LESS nephrectomy

LESS nephrectomy can be performed for both “simple” nephrectomy and radical nephrectomy, for benign and malignant pathologies, respectively. Although done for differing indications, LESS nephrectomy has similar principles and maneuvers to conventional laparoscopic nephrectomy, with slight surgeon-specific modifications to overcome the novel challenges of the single-site approach of the operation [13].

The first laparoscopic extirpative surgery in urology was the laparoscopic nephrectomy reported in 1991, and this is now a relatively straightforward case often undertaken by new trainees prior to more complex renal surgeries [14]. Since the first LESS nephrectomy was reported in 2007 by Rane *et al.*, the number has soared and remains the most common LESS urologic surgery performed [15]. A simple nephrectomy for nononcologic indications allows for morcellation of the resection specimen. The most common location for trocar placement is at the umbilicus, and morcellation obviates the need to extend the umbilical trocar site incision, maximizing the cosmetic outcome [16]. However, extension of the incision is warranted in radical nephrectomies and nephroureterectomies to allow for passage of the entire kidney specimen intact for pathologic examination and appropriate staging without compromising the oncologic efficacy of the surgery.

Rane *et al.* described their initial experience with five LESS simple nephrectomies [16]. Their indications for simple nephrectomy included chronic reflux, recurrent infections, longstanding ureteropelvic junction obstruction, stone disease, and ureteral strictures, leading to poorly functioning symptomatic kidneys. In these cases of benign renal pathology, morcellation allows for an operative scar to be hidden within the anatomic folds of the umbilicus.

Since this report of LESS simple nephrectomies, other groups have reported LESS radical nephrectomy with adequate pathologic outcomes [5, 17, 18]. LESS radical

nephrectomy has been reported through umbilical access as well as through a Pfannensteil incision. In both circumstances, the incision is commonly 4–8 cm in length for purposes of specimen extraction, unless morcellation is employed. Despite requiring a larger extraction site, LESS radical nephrectomy still requires fewer incisions compared to conventional laparoscopy, and the incision is at least partially hidden within the umbilicus or within the skin creases of the suprapubic region, depending upon approach utilized.

In a series comparing LESS simple and radical nephrectomy to conventional laparoscopic nephrectomy, Raman *et al.* reported equivalent operative time, postoperative analgesic use, length of hospitalization, and rate of complications; the LESS cohort was found to have a lower recorded estimated blood loss; however, the change in hemoglobin concentration across the two patient groups was not statistically significant [17]. More recently, a randomized controlled trial comparing LESS versus conventional multiport laparoscopic nephrectomy has demonstrated lower visual analog pain scores and decreased analgesic requirements for LESS surgery [19].

LESS partial nephrectomy

Partial nephrectomy remains a challenging operation even when performed by multiport laparoscopy. However, in selected patients, LESS partial nephrectomy has been demonstrated to be feasible and safe. LESS partial nephrectomy has been described without accessory trocars, technically replicating the conventional laparoscopic technique with careful hilar dissection for complete pedicle control, identification and excision of the tumor, and various hemostatic techniques coupled with the renorrhaphy (see Video 107.1) [5]. In efforts to minimize warm ischemia time and provide a hemostatic renorrhaphy, a 2-mm needlescopic accessory port is utilized by some experts for intracorporeal suturing [20]. As demonstrated by surgeons who have reported their experience with LESS partial nephrectomy, it is critical to convert to conventional laparoscopy in cases of limited exposure of the tumor resection site or when hemostasis is prohibitively challenging via a strict LESS approach.

Indications for conventional laparoscopic partial nephrectomy are expanding and now include resection of selected T1b tumors, central or hilar tumors, and multifocal tumors within the same kidney [21]. Currently, LESS surgery has been largely reserved for the strictest indications. In the renal LESS series reported to date, LESS partial nephrectomy was performed in a highly select patient population with ideal body habitus, limited prior abdominal surgery, and favorable tumor size and location.

LESS nephroureterectomy

In addition to LESS radical and partial nephrectomy, LESS nephroureterectomy has been reported as an oncologic application of single-site surgery of the kidney. For the treatment of upper urinary tract transitional cell carcinoma, LESS nephroureterectomy has been reported by several centers [1, 5, 6]. As with conventional laparoscopy, both retroperitoneal and transperitoneal approaches have been described. Transperitoneal LESS nephroureterectomy has been reported via an umbilical as well as a Pfannenstiel single-site incision. Through a Pfannenstiel approach, after completion of laparoscopic mobilization and freeing of the kidney and ureter, a bladder cuff was performed in an open manner [6]. In reports of the retroperitoneal as well as umbilical approach to transperitoneal LESS nephroureterectomy, specimens were extracted through a separate Gibson incision measuring between 6 and 10 cm in length, through which a formal bladder cuff excision was also performed [5, 22]. This length of incision for management of the distal ureteral segment and intact specimen extraction was acknowledged in multiple published works as a contradiction to the goals of LESS to minimize total incisional length and associated pain and cosmetic concerns.

LESS donor nephrectomy

LESS donor nephrectomy has been pursued by advanced laparoscopists only after significant experience with LESS in other renal extirpative procedures. The technique described for LESS donor nephrectomy mimics the established methods of conventional laparoscopic living donor nephrectomy first described in 1995 [23]. Important modifications unique to the LESS approach for living donor nephrectomy include the use of articulating or prebent instruments to overcome the challenges of single-port access and extra-long or bariatric instrumentation for adequate reach to the kidney, especially the upper pole and lateral aspects. Also, when selecting the mode of access for LESS donor nephrectomy, it is imperative that the surgeon(s) considers the approach to graft extraction, as time is of the essence. With this in mind, the use of a multiport device that allows for extraction and rapid re-establishment of pneumoperitoneum may be preferable to clustered trocars.

Single-site donor series have been reported by several different transplant centers with advanced laparoscopists who were facile at performing laparoscopic living donor nephrectomy [12, 24]. In this population of healthy volunteer donors, who are often related to the transplant recipients, safety is of utmost concern. Hence, the surgeon should maintain a low threshold to convert

to multiport, hand-assisted, or open surgery in cases with a difficult anatomic approach or allograft procurement [1].

However, it is in this same population of young, healthy volunteers that the provision of a cosmetically superior result may be most valued by the patient. The initial publications on this less invasive approach to renal allograft procurement describe efficacy and feasibility of LESS donor nephrectomy.

A single comparative study reporting a single-surgeon experience of six LESS cases matched to six conventional laparoscopic donor nephrectomies reported statistically comparable perioperative parameters, renal allograft characteristics, and postoperative pain [12]. Perioperative parameters evaluated and compared included operative time, warm ischemia time, estimated blood loss, and length of hospitalization. Postoperative pain was assessed by narcotic requirements and patient-reported scores on a visual analog pain scale. Notably, the median pain score reported at discharge in the cohort of LESS donor nephrectomy was zero on a 0–10 visual analog pain scale. None of the six LESS cases required conversion to conventional laparoscopy to complete the case safely, and all allograft specimens were adequate for successful transplantation and immediate function once implanted.

A matched-pairs comparison of LESS donor nephrectomy to conventional donor nephrectomy revealed a quicker convalescence in the patient cohort undergoing LESS donor nephrectomy [25]. Parameters improved by the LESS approach included time on oral analgesics, time off work, and time to "100% recovery," as noted by patient questionnaires. In this study, warm ischemia time was statistically significantly higher in the LESS cohort; however, allograft function was noted to be immediate and comparable across the two groups.

LESS adrenalectomy

The first conventional laparoscopic adrenalectomy was reported in 1992 [26]. Since then, laparoscopic adrenalectomy has been accepted as a feasible and safe minimally invasive option for the surgical treatment of various adrenal neoplasms [27]. For small to mid-size adrenal lesions, laparoscopic adrenalectomy has become standard practice not only for urologists but also general surgeons at some centers. Debate exists regarding the efficacy of laparoscopy for the treatment of known or suspected adrenal cortical carcinoma, particularly for larger masses.

One of the earliest reports of LESS adrenalectomy was of retroperitoneoscopic adrenalectomy via a 4.5-cm trocar without the use of insufflation [28]. In this report, 53 patients with adrenal tumors were treated successfully via this approach and one patient (1.9%) required conversion to open surgery secondary to excessive blood loss from an adrenal vein injury.

In a contemporary series, nine patients undergoing LESS adrenalectomy for benign adenoma were compared to 17 patients undergoing conventional laparoscopic adrenalectomy [29]. Patients were matched with regard to age, sex, surgical indications, and tumor size. Operative time, blood loss, and hospital stay were found to be equivalent. The LESS group demonstrated a shorter period of postoperative intravenous patient-controlled analgesia use.

Reconstructive surgery

LESS pyeloplasty

Pyeloplasty is the most common reconstructive upper tract urologic surgery performed. With the advent of laparoscopic pyeloplasty in 1993, there was a significant movement toward a minimally invasive approach to the otherwise large, muscle-traversing flank approach for open pyeloplasty, which was the former standard [30]. Since the development and diffusion of laparoscopic pyeloplasty by urologists, both dismembered and V–Y laparoscopic pyeloplasties have been performed in large series with reliable postoperative outcomes [31, 32].

As with living donor nephrectomy, patients undergoing pyeloplasty are often young and healthy, without malignant pathology, and cosmesis may be of greater concern to them. A cohort of LESS pyeloplasty patients demonstrated a younger mean and median age when compared to other LESS upper tract operations in a single institution experience of upper tract urologic LESS [5]. Heightened efforts to minimize the overall incision burden and subsequent appearance of cutaneous scars in this population seem appropriate. Ongoing research is aimed at further defining the quality of life and cosmetic advantages that LESS urologic surgery may provide.

LESS pyeloplasty can be performed with or without the use of accessory trocars [5]. All techniques and associated procedures can be performed via LESS, including dismembered pyeloplasty, V–Y pyeloplasty, pyeloscopy, and stone extraction. We advocate flexible cystoscopy and placement of a 7F, 28-cm double-pigtail ureteral catheter prior to commencing with the LESS portion of the procedure. Other surgeons advocate a smaller 6F stent to facilitate positioning of the scissor blade between the stent and ureteral wall, and thereby facilitating spatulation. Still other surgeons prefer an antegrade approach to stent placement during laparoscopy. Although we consider rigid straight laparoscopic instruments to be sufficient for nearly all LESS surgery, spatulation of the ureter may be facilitated by the use of articulating scissors in some cases.

Conventional laparoscopic salvage pyeloplasty has been reported with promising results [33, 34]. However, to date, LESS pyeloplasty is reserved for idealized patients undergoing primary pyeloplasty for congenital ureteropelvic junction obstruction. LESS pyeloplasty can be performed in the setting of a crossing vessel, as dismembered, transposed pyeloplasty can be performed effectively.

Short-term postoperative outcomes have been reported for LESS pyeloplasty and compared to historical controls undergoing conventional laparoscopic pyeloplasty. In a study reported by Raman *et al.*, LESS pyeloplasty resulted in comparable perioperative and functional outcomes [35]. All perioperative parameters were equivalent, except for operative time and estimated blood loss, which were found to be significantly lower in the LESS cohort of patients.

A multi-institutional study by Schwartz *et al.* showed LESS pyeloplasty to be a safe option with success rates equivalent to conventional laparoscopic pyeloplasty [36]. In this series, the only clear benefit noted in the period of short follow-up was that of minimized incision size and postoperative scar formation, although postoperative pain and analgesic requirements were not assessed.

Ablative surgery

LESS cryoablation

Cryoablation has been demonstrated as an oncologically effective means of providing focal ablation therapy for the treatment of small renal masses, maintaining a nephron-sparing result [37]. Both laparoscopic and percutaneous, image-guided approaches have been well-described for renal cryoablation. Benefits of the laparoscopic approach to renal cryoablation include direct visualization of probe placement, monitoring the ice-ball formation visually or with intraoperative ultrasonography, and the means to mobilize bowel or other adjacent structures safely away from the area of focal ablation [38]. Transperitoneal as well as retroperitoneoscopic entry have been reported, differentially used based primarily on the anatomic location of the renal mass being ablated.

The technique for LESS cryoablation, using both transperitoneal and retroperitoneal approaches, was first reported in a human series in 2008 [39]. Since this initial report, LESS cryoablation has been reported by a number of different institutions as part of larger urologic LESS series in the literature [1]. To date, the literature has demonstrated LESS cryoablation to be a successful approach with acceptable perioperative parameters when compared to conventional laparoscopy. In a small number of cases, there was conversion to conventional laparoscopy [39]. However, LESS cryoablation is at a very early stage of the learning curve of LESS surgery.

Renal cryoablation provides an ideal opportunity for LESS because there is no specimen necessitating an extraction site. Also, intracorporeal manipulation is limited to mobilization of adjacent organs and intraoperative imaging with ultrasonography, whilst other LESS renal surgeries require advanced intracorporeal suturing techniques or vascular clamping and manipulation that are more easily achieved with the triangulation provided by conventional multi-port laparoscopy.

LESS cyst ablation/decortication

Laparoscopic and LESS management of renal cysts provides minimally invasive access to either aspirate and sclerose the cyst cavity, ablate the lining, or decorticate symptomatic renal cysts. Decortication by excision of the cyst wall with luminal fulgration using either an argon beam coagulator or electrocautery provides the most durable long-term outcome based upon rates of recurrence [40, 41].

Series of LESS cyst decortication have been presented in larger LESS series encompassing multiple operative LESS cases [1, 22, 42]. LESS cyst decortication has been reported through periumbilical access providing a transperitoneal approach as well as a retroperitoneal approach through a multichannel access port placed in the flank. Operative techniques vary based upon the location of the renal cyst being targeted as well as the complexity of the dissection required to expose the cyst for decortication. A combination of standard laparoscopic and articulating laparoscopic instruments has been reported to aid in these LESS cases. Also, one report cited use of an operative laparoscope to further minimize the access ports required, allowing for successful retroperitoneal LESS cyst decortication [7].

Patients with large renal cysts, reported as large as 15 cm, have been safely and successfully managed with LESS surgery, with minimal intraoperative blood loss and discharge commonly on the first or second postoperative day [1, 7, 42]. The length of hospitalization is likely a result of the early learning curve of LESS surgery. As with laparoscopic renal cryoablation, conventional laparoscopic cyst decortication has been reported as an ambulatory operation in experienced centers [43]. In future, LESS surgery for such ablative procedures should be tested for its clinical durability but also should be compared to conventional laparoscopy for the period of postoperative convalescence, since conventional laparoscopy already provides such remarkable outcomes.

Future of LESS for upper tract urologic surgery

Dissemination of advances in surgical technique is dependent upon the realized value of the advance. Furthermore the technique must prove reproducible beyond selected centers of excellence. LESS has proven its versatility based upon the wide range of urologic operations for which it has been successfully employed as an extension of conventional laparoscopy. Furthermore, as experience with LESS augments in some centers, more novice surgeons, including residents and fellows enrolled in urology training programs, are being exposed to these new techniques within an apprenticeship model. Also, as skill centers are using inanimate box trainers and electronic simulators as an adjunct aide in laparoscopic training outside the operating room, new LESS training modules should be developed to augment the breadth of these simulator platforms.

As surgeons become more experienced with LESS, expand the indications for LESS, and diffuse the techniques throughout resident training programs and the community, the number of cases will inevitably increase. This will in turn provide valuable data to evaluate the comparative efficacy and potential benefits of LESS over conventional laparoscopy and direct the field appropriately.

Further research efforts are also underway to develop improved instrumentation and access platforms to facilitate LESS. Motorized articulating instruments and robotic platforms will become available that will help overcome the inherent challenges of single-site surgery. Published reports have described the use of the da Vinci Surgical System as an adjunct to LESS urologic techniques [8, 44]. Currently under investigation are magnetic anchors and intracorporeal robotic mechanisms with the goal to minimize the number and length of incisions, as well as to provide better triangulation in LESS cases [45].

In future, it is imperative that prospective studies focused on patient quality of life and postoperative satisfaction with cosmesis are pursued. Further study is also necessary to elucidate any potential benefits with respect to pain and convalescence.

CHAPTER 108

Laparoendoscopic Single-Site Lower Tract Surgery

Mihir M. Desai

USC Institute of Urology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Introduction

Laparoscopic and robotic surgery has been increasingly used to perform pelvic urologic procedures. As surgeons have become more experienced with complex laparoscopic procedures, efforts are ongoing to further reduce the morbidity and improve the cosmesis of conventional multiport laparoscopic surgery. Laparoendoscopic single-site (LESS) surgery is a recently christened variant of laparoscopic surgery that encompasses a group of closely related techniques that perform laparoscopic and robotic procedures through a single skin incision, typically concealed within the umbilicus. Since the initial LESS nephrectomy performed about 3 years ago [1, 2], there have been multiple reports demonstrating technical feasibility of LESS surgery in performing various urologic procedures. Initially used for relatively straightforward upper tract procedures, with growing experience and availability of purpose-specific instrumentation, the use of LESS surgery has been carefully extended to pelvic urologic procedures. This chapter reviews the various clinical applications of LESS in pelvic urologic surgery.

Instrumentation

Improvements and refinements in instrumentation and technology have contributed to the recent surge in LESS procedures across surgical specialties. These include custom-specific, single-access devices, articulating and bent instrumentation, deflecting tip optics, and needlescopic instrumentation (see Chapter 106). In the future innovative intracorporeal instruments and custom-specific robotic platforms are likely to further enhance the scope and application of LESS surgery.

Clinical pelvic applications

After its successful use for upper tract surgery, various authors have successfully performed pelvic surgery through a single incision (Table 108.1). The various LESS urologic pelvic procedures include radical prostatectomy, radical cystectomy, benign prostatic hyperplasia (BPH) enucleation, and sacrocolpopexy.

Radical prostatectomy

Several authors have successfully performed LESS radical prostatectomy. Kaouk *et al*. reported LESS radical prostatectomy in four patients with prostate cancer. Selection criteria were stringent and included early (T1c) prostate cancer, body mass index (BMI) of 35 or less, and absence of prior pelvic surgery [3]. All procedures were performed using a multichannel single-port device inserted transumbilically without the need of any ancillary extraumbilical ports. The vesicourethral anastomosis was performed using free-hand laparoscopic suturing. The mean operative time was 3.25 h for the prostatectomy and 1.1 h for the anastomosis, estimated blood loss (EBL) was 288 mL, duration of hospitalization was 2.4 days, and duration of catheterization was 2 weeks. One patient developed a rectourethral

Table 108.1 Laparoendoscopic single-site surgery (LESS): pelvic applications in urology.

Study	LESS procedure	Number of patients	Operative time (h)	Number of complications	Comments
Kaouk *et al*. [3]	Radical prostatectomy	4	4.4	1 rectourethral fistula	No extraumbilical ports Two patients had positive margins Three patients were continent Four patients had undetectable PSA at 1 month
Barrett *et al*. [4]	Radical prostatectomy	1	2.5	0	Used the da Vinci Si System Used one extraumbilical 5-mm port Negative surgical margins Functional results not reported
Rebenalt *et al*. [5]	Radical prostatectomy	1	4.9	0	Extraperitoneal laparoscopic approach
Desai *et al*. [7]	Simple prostatectomy	34	2	8	Procedure performed laparoscopically/robotically One mortality in a Jehovah's Witness All 33 remaining patients had improved IPSS and Qmax
White *et al*. [9]	Sacrocolpopexy	10	2.5	0	Technically feasible in all 10 cases Outcomes comparable to robotic and conventional laparoscopic sacrocolpopexy on retrospective comparison
Kaouk *et al*. [8]	Radical cystectomy	3	5.25	0	No extraumbilical ports Diversion performed extracorporeally Mean lymph node yield 16 No recurrence with at least 2 years follow-up

PSA, prostate-specific antigen; IPSS, international prostate symptom score.

fistula and two had positive surgical margins. Three patients used 0–1 pads and prostate-specific antigen (PSA) was undetectable in all patients at 1-month follow-up. Barrett *et al*. performed laparoscopic and robot-assisted radical prostatectomy in the human cadaver and subsequently extended robotic LESS to perform a procedure clinically [4]. The procedure was performed by placing three robotic ports (da Vinci Si; Intuitive Surgical, Sunnyvale, CA, USA) positioned through a 3-cm skin incision. The authors employed an additional 5-mm extraumbilical port through which a drainage tube was exited at the conclusion of the procedure. Rabenalt *et al*. reported the first clinical experience with a LESS extraperitoneal radical prostatectomy. A 2-cm midline infraumbilical incision was made and the preperitoneal space was developed using a balloon dilator. The Triport (Olympus Medical, Tokyo, Japan) was inserted through the incision to create an air-tight seal to the extraperitoneal space. Using straight, as well as prebent instruments, the procedure was completed successfully with an operative time of 290 min and an EBL of 100 mL [5].

Simple prostatectomy

LESS techniques have been successfully used to enucleate large volume adenoma in patients with symptomatic BPH. Sotelo *et al*. initially performed a LESS adenomectomy using the transperitoneal approach with a single-port device inserted in the umbilicus [6]. The bladder was dissected to enter the space of Retzius and the adenomectomy performed after making a transverse incision through the anterior bladder wall just proximal to the bladder neck. Desai *et al*. performed BPH enucleation using the transvesical approach (STEP procedure) in 34 patients with large-volume BPH. Mean age was 69 years, BMI was 26 kg/m^2, and American Society of Anesthesiology class was 2 [7]. The mean prostate volume estimated by transrectal ultrasonography was 102.5 mL and the mean baseline PSA level was

6.7 ng/mL. A novel single-port device was inserted percutaneously into the bladder through a 2–3-cm incision in the suprapubic skin crease. After establishing pneumovesicum, the prostate adenoma was enucleated transvesically using standard laparoscopic instruments, and the adenoma was extracted in pieces through the port. Digital assistance expedited enucleation of the apical adenoma in 19 (55%) cases. Transvesical enucleation was completed in all 34 cases; the mean operative time was 116 min, and the EBL was 460 mL. There was one death from postoperative bleeding from uncontrolled coagulopathy in a Jehovah's Witness who refused a transfusion of blood and blood products. There were three complications during STEP (one death, one bowel injury, and one hemorrhage) and five afterwards (four bleeding, one epididymo-orchitis). Open conversion was necessary in two patients for complications, and extension of the skin incision by 1–2 cm was necessary in two to expedite apical digital enucleation. The mean hospital stay was 3 days and mean analog pain score at discharge was 2. All 33 patients (excluding the patient who died) were voiding spontaneously at a maximum follow-up of 8 months, with a mean American Urological Association symptom score of 3, a maximum urinary flow rate of 44 mL/s, and a postvoid residual of 30 mL at the latest follow-up. No patient developed urinary incontinence. STEP is an effective treatment option for selected patients with large-volume obstructive BPH. Under pneumovesicum using laparoscopic visualization, the entire adenoma can be effectively enucleated and expeditiously extracted through the novel single port. Comparison of the STEP procedure with other open and transurethral techniques will determine its place in the surgical treatment of large-volume BPH.

Cystectomy

Kaouk *et al*. recently presented the technical feasibility of LESS radical cystectomy in two male and one female patients with muscle invasive bladder cancer [8]. All three procedures were successfully completed via a single transumbilical access. Mean operative time was 315 min, blood loss was 217 mL, and hospital stay was 6 days. Urinary diversion was performed extracorporeally by minimal extension of the umbilical incision. Pelvic lymph node dissection was performed up to the aortic bifurcation with a mean lymph node yield of 16. Pathologic evaluation revealed negative surgical margins and there was no recurrence with a minimum follow-up of 2 years. Despite this encouraging initial experience, urothelial cancer is a potentially lethal disease and oncologic factors are likely to outweigh cosmetic issues in management decisions. As such, more data are necessary before LESS techniques are used more frequently for muscle invasive bladder cancer.

Sacrocolpopexy

Laparoscopic and more recently robotic sacrocolpopexy have been performed as an alternative to open surgery for treatment of female pelvic organ prolapse. White *et al*. recently reported their experience in 10 patients undergoing LESS sacrocolpopexy for pelvic organ prolapse [9]. The procedures were performed exclusively using a single-port device inserted transumbilically through a 1.8-cm incision. Two strips of polypropylene mesh were inserted paravaginally through 1-cm incisions just lateral to the labia majora. The mesh was affixed to the vaginal apex and then to the sacral promontory with appropriate tension using intracorporeal suturing performed through the single-port device. The authors retrospectively compared their experience with patients undergoing laparoscopic (n = 10) or robotic (n = 10) sacrocolpopexy. The LESS approach was equivalent to the laparoscopic and robotic approaches in terms of operative time (160 vs 151 vs 150 min, respectively), EBL (48 vs 65 vs 87 mL, respectively), length of hospitalization (1.5 vs 1.6 vs 1.6 days, respectively), and pain levels as measured on a visual analog scale (0.7 vs 2.1 vs 1.4, respectively). All 27 patients who were available for 3- and 6-month follow-up reported adequate symptomatic relief and reduction of the pelvic organ prolapse on repeat assessment, attesting to the short-term equivalence in efficacy of the LESS approach compared to the laparoscopic or robotic approach.

Miscellaneous procedures

Various other LESS pelvic procedures have been anecdotally reported in the urologic literature. These include varicocelectomy [10], ureteral reimplantation [10–12], and vesicovaginal fistula repair (P. Rao, unpublished study). Small numbers and limited outcome data significantly limit the widespread use of these procedures using LESS techniques.

Conclusions

The recent application of LESS surgery in urology has been extended to select pelvic procedures. Generally, the number of procedures performed and outcome data for pelvic LESS surgery are scant compared to upper tract procedures. Increasing experience and potentially availability of an effective and dedicated robotic platform may facilitate more widespread dissemination of urologic pelvic LESS surgery.

SECTION 7
Image-Guided Diagnostics and Therapeutics

CHAPTER 109
Radiologic Diagnosis of Renal Masses

Gail S. Smith, Carolyn K. Donaldson & Richard M. Gore
Department of Radiology, North Shore University Health System, University of Chicago, Pritzker School of Medicine, Evanston, IL, USA

Introduction

Over that last 25 years, the evaluation of renal masses has been revolutionized by technical advances in ultrasound, multidetector computed tomography (MDCT), and magnetic resonance imaging (MRI) [1–4]. It is estimated that 50% of people over the age of 50 years have at least one renal mass that can be detected on cross-sectional imaging [5–7]. Most of these lesions are benign simple cysts that can be diagnosed with confidence and require no further evaluation or treatment [8]. However, most renal neoplasms are now found incidentally while evaluating the patient for other suspected pathology [1]. The role of the radiologist is not only to detect these renal lesions, but also to distinguish between benign and malignant masses, and to help direct the management of these lesions.

Over the past decade, the treatment of renal masses has become increasingly individualized with therapeutic options, including radical nephrectomy, laparoscopic nephron-sparing surgery, and laparoscopic or imaging-guided cryotherapy and radiofrequency ablation [9–14]. This chapter reviews the role of CT, MRI, and ultrasound in guiding the increasingly sophisticated process of characterizing and managing renal masses. Guidelines concerning the most efficacious use of the various imaging modalities with a view towards optimizing patient management are presented.

Imaging techniques

Multidetector computed tomography

Recent improvements in MDCT technology allow thinner collimation and faster scanning that provides multiphasic, high-resolution images of the kidneys. These hardware developments coupled with advances in three-dimensional (3D) imaging software and the availability of cheaper data storage capacity have provided new opportunities for imaging renal and urinary tract pathology. Isotropic imaging of the kidneys, ureters, and bladder is now possible, providing 2D multiplanar reformations (MPR), CT urography (CTU), and 3D imaging formats, with minimal artifacts, all derived from a single data acquisition [15, 16]. The kidneys can be scanned in less than 5 s, allowing for acquisition of thin-section images during the corticomedullary, nephrographic, and excretory phases. This multiphasic evaluation permits high-resolution imaging of not only the renal parenchyma but also the renal vasculature and collecting system.

Evaluation of a renal mass by CT requires a dedicated multiphasic CT protocol which may include the following scans: precontrast; arterial phase (15–25 s delay); corticomedullary phase (35–80 s delay); nephrographic phase (85–180 s delay); and excretory phase (>3 min delay). To reduce the patient radiation dose, the precontrast,

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

nephrographic phase, and excretory phase scans are the ones most commonly obtained [15–17].

Noncontrast scans of the kidneys are performed initially to evaluate for the presence of fat or calcification in the mass and to detect nephrolithiasis. This scan also provides a baseline from which to quantify lesion enhancement on postcontrast scans. The scans performed during the arterial or corticomedullary phase, while limited for mass visualization, nicely display the renal vasculature, which is critical for surgical planning, particularly when partial nephrectomy is being considered. Arterial phase scans best show small hypervascular neoplasms and the renal arteries. The nephrographic phase optimizes mass visualization. The delayed phase scans are helpful in assessing the relationship of the renal mass to the renal collecting system and also visualizing the remainder of the urinary tract. The data from these various series can then be reconstructed at thinner intervals and transferred to a workstation where multiplanar reformatted images, maximum intensity projection (MIP) images, and 3D volume-rendered images can all be created [15–17].

Contrast enhancement and subsequent de-enhancement are characteristic features of renal malignancies. A renal lesion is considered to have enhanced when its density increases by more than 20 Hounsfield units (HU). If the density of the lesions increases by between 10 and 20 HU, it is considered indeterminate for enhancement and requires further testing. While these criteria seem straightforward, the accuracy of determining enhancement varies based on the type of CT scanner used as well as technical factors, including the kilovoltage and amperage of the X-ray beam, pixel size, image noise, slice thickness, beam hardening artifacts, and artifacts related to large body habitus. The size of the lesion is also important because volume averaging commonly occurs in lesions smaller than 10 mm in size.

Pseudoenhancement occurs when a cyst, usually of less than 2 cm, appears to artifactually enhance because it is surrounded by strongly enhancing parenchyma. This typically occurs during peak renal enhancement and should be suspected when a lesion is homogeneous and measures less than 10 HU on an unenhanced CT scan [18–21].

Rising healthcare costs and increasing radiation doses from MDCT have given rise to concerns about over- and inappropriate use of CT in modern medical practice. Using data from the Hiroshima and Nagasaki atomic explosions, radiation scientists and physicists have suggested that the linear nonthreshold theory for radiation-induced carcinogenesis is valid also at the low radiation doses associated with CT scanning, contending that MDCT will contribute to a greater incidence of cancer in the future. Others disagree over the applicability of such data to CT scanning, emphasizing that whereas the data from atomic explosions reflect a single exposure, patients are exposed to effects of cumulative radiation doses from repeat or follow-up CT scanning. They also contend that the biologic response to particulate exposure from the former atomic explosions may not be similar to the response to X-ray exposure from CT scanning [22].

Recently, all MDCT vendors have seen the importance of radiation dose reduction and have placed extensive effort into optimizing the dose while maintaining and improving applications of their systems. Better detector configurations, scanner speed, automatic exposure control techniques, prepatient X-ray beam collimation, noise-reduction filters, and prepatient bowtie and other physical X-ray beam filters have been implemented to reduce the radiation dose [22].

There are three major factors that potentially contribute to the delivery of high radiation doses from MDCT evaluation of the urinary tract: the replacement of conventional radiography with CT for the evaluation of stone disease and hematuria; the need for multiple follow-up CT studies; and the use of multiphase MDCT protocols [22].

Patients with nephrolithiasis are at a greater risk of having follow-up CT studies, leading to potentially high cumulative effective doses. The mean effective dose for a single-stone protocol study using MDCT is approximately 8.5 mSv. Even higher radiation doses are associated with CTU than with stone protocol CT, because scan protocols use up to four phases: noncontrast, corticomedullary, nephrographic, and excretory. If all scan parameters are kept identical, a four-phase MDCT exam exposes patients to a fourfold higher radiation dose (34 mSv). CT scanning for evaluation of renal masses, hematuria, and renal donors usually is performed using multiphase protocols, increasing the radiation dose substantially. In patients with renal cell carcinoma (RCC) and transitional cell carcinoma (TCC) who will have multiple follow-up examinations, MRI and magnetic resonance urography (MRU) should be considered as an alternative to multiphase MDCT as a means of reducing radiation dose to the patient [22].

Magnetic resonance imaging

Significant advances in MRI hardware and software with routine use of phased-array coils and parallel imaging permit fast and high spatial resolution imaging of the kidneys. Short breath-hold scans can produce superb multiphase renal images without significant peristaltic or respiratory motion artifacts [23–26]. The following imaging sequences should be obtained when evaluating a renal mass with MRI:

- Coronal T2-weighted single-shot turbo spin-echo sequence to serve as a localizing scan;

• Axial T2-weighted gradient and spin-echo sequence with fat suppression to search for renal mass invasion of the adjacent fat; a dual-echo axial T1-weighted gradient-echo sequence with in- and opposed-phase images to search for fat within the tumor;
• Axial T1-weighted fat-suppressed gradient-echo sequence for dynamic imaging using 20 mL of intravenous gadolinium with pre- and post-contrast images obtained during the arterial, corticomedullary, and nephrographic phases to assess tumor vascularity.

The physiologic principles behind the various dynamic postcontrast phases described in the MDCT section also hold true for dynamic MRI [27].

MRI is generally employed as a secondary imaging test when better characterization of a mass found on MDCT or ultrasound is needed. MRI is used as a primary imaging test in patients who have a severe allergy to iodinated contrast or who are pregnant. Because of the risk of nephrogenic systemic fibrosis, MRI with gadolonium should not be performed in patients with poor renal function. MRI may become more commonly employed for following renal lesions given the increased concerns regarding cumulative radiation dose. This is particularly applicable in young patients.

The chemical-specific tissue characterization capabilities of MRI are particularly helpful in characterizing certain types of renal lesion. Confident characterization of hemorrhagic cysts can be problematic on CT because the lack of enhancement of a small, dense renal mass may be difficult to confirm. Hemorrhagic cysts usually have high signal on T1-weighted MRI. The signal intensity of hemorrhagic or proteinaceous cysts on T2-weighted images is variable, ranging from a low to mildly increased signal compared with renal parenchyma, but usually a lower signal than seen in adjacent cerebrospinal fluid or other simple cysts. The combination of high signal on T1-weighted images and the lack of enhancement on MRI are diagnostic of a hemorrhagic renal cyst [23–27].

MRI is also useful in characterizing complex renal cysts. Septations within complex renal cysts that are vague on CT are readily depicted with MRI. Because fluid signal on T1-weighted images is usually darker than the low attenuation seen on CT, contrast enhancement within the septations is usually more apparent on MRI than on CT, especially with subtraction images [23–27]. MRI is more sensitive than CT in the detection of macroscopic fat within lesions such as angiomyolipomas (AMLs). While most AMLs can be characterized with CT, it may be difficult to obtain accurate CT density measurements on small lesions. MRI can confidently characterize AMLs in two ways. First, frequency-selective chemical fat suppression will result in subjective signal loss within fat-containing regions of the lesion. Secondly, chemical shift artifact will show a sharp, dark interface between the AML and normal renal parenchyma [23–27].

MRU is an exciting and evolving technique, which is clinically useful in the evaluation of patients with urinary tract obstruction, hematuria, surgically-altered anatomy, and congenital abnormalities, as well as in pregnant and pediatric patients or when ionizing radiation needs to be avoided. There are two major types of MRU techniques: static fluid MRU and excretory MRU. The first technique employs heavily T2-weighted sequences to image the urinary tract as a static collection of fluid. It works best in patients with obstructed and dilated collecting systems. In excretory MRU, intravenous gadolinium is administered and imaging is performed during the excretory phase of enhancement to better demonstrate nondilated renal collecting systems [24–27].

Ultrasound

Although CT is the premier imaging test in patients with suspected renal pathology, ultrasound is often the first imaging test ordered for renal evaluation. Despite its technical limitations, a large number of renal tumors can be correctly characterized sonographically. Recent advances in gray-scale and color-flow Doppler techniques, as well as tissue harmonics, have enhanced the ability of ultrasound to distinguish solid from cystic lesions, and to make the diagnosis of a simple renal cyst [28–31]. Sonography is employed on a daily basis for evaluating lesions detected incidentally on CT that are not clearly simple cysts.

Lesions which are felt to represent hyperdense cysts either contain hemorrhage or proteinacious fluid. Those containing proteinacious fluid are typically simple on ultrasound, whereas those containing blood can appear heterogeneous and partly solid.

Ultrasound is useful in evaluating complex cystic lesions and detecting septations or minimal mural nodularity. This technique, however, is operator dependent and can be extremely limited in obese patients or when there is a large amount of adjacent bowel gas. Sonography can be quite useful for assessing the presence of renal vein thrombus with 75% sensitivity and 96% specificity, and 100% accuracy for detecting thrombus in the inferior vena cava [30, 31]. Intraoperative ultrasound has become a useful tool in guiding the surgeon during nephron-sparing surgery of small renal cell neoplasms.

Positron emission tomography–computed tomography

Most malignancies exhibit increased metabolic activity leading to increased utilization of glucose. Positron emission tomography (PET) imaging exploits the fact

that the glucose analog, F-18-2-fluoro-2-deoxy-glucose (FDG), shows increased intracellular accumulation in malignant tissue. PET–CT is a fixed combination of PET and CT scanners in a combined imaging system. The nearly simultaneous data acquisitions lead to minimization of spatial and temporal mismatches between modalities by eliminating the need to move the patient during the examination. The result is a fused image that provides biologic and anatomic information. Imaging metabolic information of tumor tissue often provides more sensitive and specific information concerning the extent of malignancy than anatomic information alone [32–35].

Although FDG-PET is a well accepted method for the detection and staging of a number of malignancies, including lung, breast, colorectal, and esophageal cancer, it currently has a limited role in evaluating RCC. Several studies have shown that FDG-PET has a high specificity, but its sensitivity is inferior to that of CT and MRI in the evaluation of suspicious primary or metastatic RCC. FDG-PET surpasses the 90% sensitivity mark only for lesions at least 2 cm in diameter [32, 33]. Although there are studies that report sensitivity of FDG-PET to be as high as 94%, it is generally accepted that malignancy cannot be ruled out with a negative study. RCCs have inconsistent FDG uptake, which may be due to hypo- or iso-metabolism relative to background tissues, lack of accessibility of FDG, or heterogeneity of glucose transporter expression [34, 35].

Renal mass characterization in the patient with renal insufficiency

The characterization of renal masses is problematic in patients with renal insufficiency as iodinated contrast is potentially nephrotoxic and intravenous gadolinium is associated with a small risk of nephrogenic systemic fibrosis. In most cases, sonography can characterize a Bosniak type I and II cyst. Noncontrast-enhanced MRI is also useful in confidently characterizing cysts. Neither modality will provide information about the vascularity and contrast enhancement of a renal lesion.

Diffusion-weighted imaging (DWI) is a noncontrast MRI technique that has shown great promise in the characterization of renal lesions. DWI measures the Brownian motion of water molecules in biologic tissues, which has been shown to be inversely proportional to cellular density, presumably because increased cellular density limits water diffusion in the interstitial space. The apparent diffusion coefficient (ADC), a quantitative parameter measured from DWI, has been shown to have the potential to differentiate benign and malignant masses [25, 33].

One preliminary study aimed at investigating the potential role of DWI in the characterization of renal tumors showed that renal lesions with different tissue contents may have different diffusion characteristics. Solid tumor tissue has lower ADC values than necrotic or cystic tumor tissue, whereas necrotic or cystic tumor tissue has lower ADC values than benign cysts. This distinction is important for differentiating benign cysts from extensively necrotic or cystic tumors that may demonstrate little or no contrast enhancement and an imaging appearance similar to a complex benign renal cystic lesion on conventional MRI [33].

DWI offers the potential to differentiate solid RCCs from oncocytomas and characterize the histologic subtypes of RCC. DWI might be a reasonable, albeit less accurate, alternative to contrast-enhanced MRI for renal mass characterization in patients with contraindications to gadolinium-based contrast [25, 33].

Cystic renal masses

Incidentally discovered renal cysts are commonly found on cross-sectional imaging studies. Strict imaging criteria were developed by Bosniak in 1986 [36] to categorize renal cysts as benign, malignant or indeterminate (Table 109.1), and to guide the management of these lesions. The Bosniak classification has since undergone several modifications [37–40]. Although initially described for lesions found on CT, the criteria can be applied to MRI with overall similar accuracy [41]. In some cases, MRI may depict additional septae, thickening of the wall or

Table 109.1 Bosniak classification of cystic renal masses.

Category	Features
I	A simple water-attenuation cyst with a hairline-thin wall, without septa, calcification, or solid components; no contrast enhancement
II	Bosniak type I with a few thin septa or fine calcifications in the wall or septa
	Sharply marginated, nonenhancing, uniformly high-attenuation lesions of <3 cm
IIF	Bosniak type II cystic lesion with minimal enhancement of a hairline-thin septum or wall, or minimal thickening of the septum or wall; the cyst might contain calcification that might be nodular and thick, but there is no contrast enhancement
	Uniformly high-attenuation lesions of >3 cm
III	Bosniak type IIF cystic lesion with thickened irregular walls or septa, and contrast enhancement
IV	Enhancing soft tissue components or mural nodules

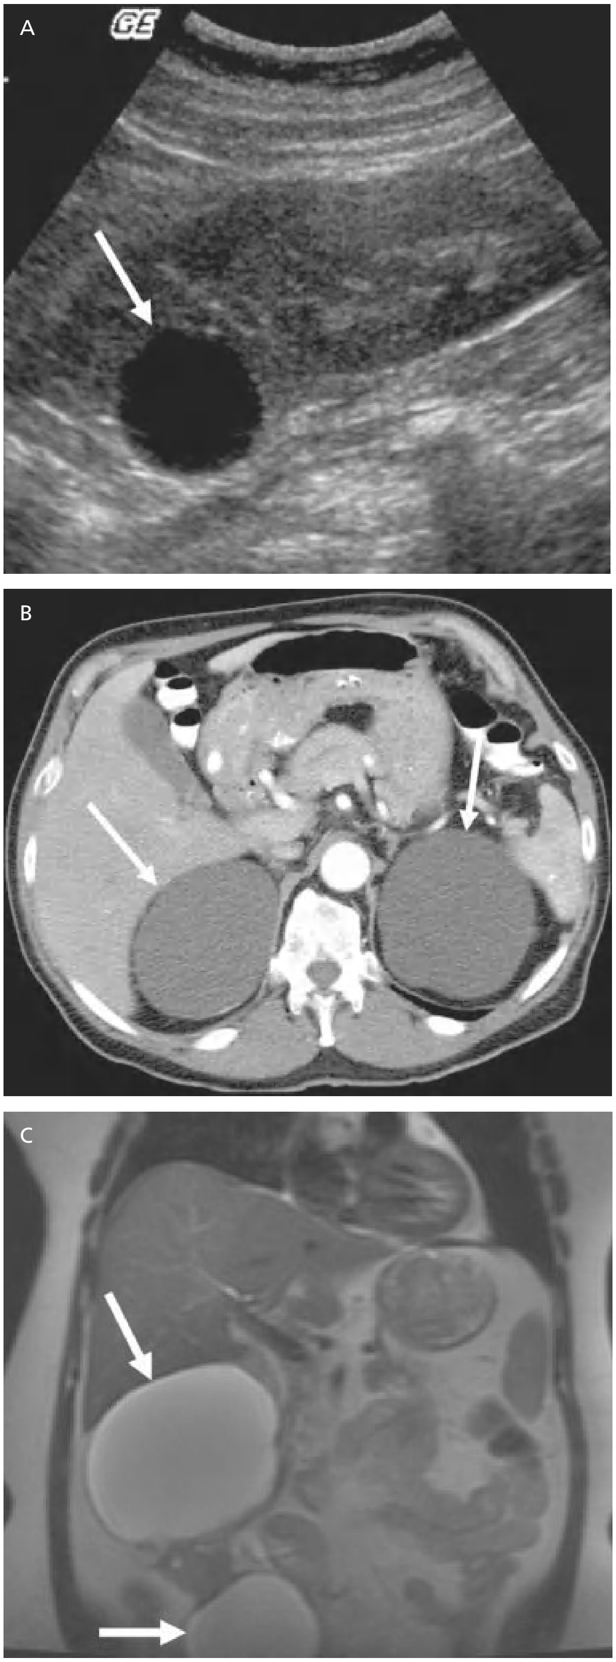

Figure 109.1 Bosniak type I renal cyst. (A) Longitudinal sonogram shows a well-marginated, anechoic cyst (arrow) along the posterior aspect of the upper pole of the right kidney. (B) Axial contrast-enhanced CT scan shows large, bilateral, nonenhancing water density renal cysts (arrows). (C) Coronal T2-weighted MR image shows well-marginated, hyperintense cysts (arrows) with paper-thin walls in the upper and lower poles of the right kidney. Note the absence of mural thickening or nodularity.

enhancement, which may lead to an upgraded Bosniak classification.

Category I lesions

These lesions are benign simple cysts requiring no further diagnostic imaging or follow-up (Figure 109.1). On CT, these lesions must have a paper-thin wall, entirely fluid attenuation measuring between 0 and 20 HU, and demonstrate no enhancement following the intravenous administration of contrast. These lesions do not contain septations or calcifications.

Category II lesions

These lesions are also benign, but are minimally complicated (Figure 109.2). They may contain a few paper-thin septations. They may also contain fine curvilinear, mural or septal calcification. This category also includes hyperattenuating cysts that measure less than 3 cm, and are round and sharply marginated, with at least one-quarter of the lesions extending outside the renal parenchyma. Most importantly, they must demonstrate uniform high attenuation and no enhancement with intravenous contrast. Cysts that measure between 20 and 40 HU are usually proteinacious cysts, and with a density of greater than 40–50 HU are likely to be hemorrhagic. The latter will appear complex on ultrasound. They may appear solid or semi-solid due to clot retraction and can be miscategorized by ultrasound.

In one study, Jonisch *et al.* attempted to differentiate high-attenuation renal cysts from RCCs on unenhanced CT scans [16]. They retrospectively evaluated the attenuation values and degree of uniformity/heterogeneity in 56 hyperdense renal cysts and 54 RCCs. The mean attenuation for hyperdense cysts was 53 HU and for RCCs was 38 HU, but there was significant overlap when evaluating attenuation values alone. However, when evaluating uniformity versus heterogeneity of the lesion, the authors concluded that a homogeneous, hyperattenuating renal masses with an attenuation of 70 HU or greater had a 99.9% likelihood of being a benign, high-attenuation renal cyst. Most RCCs in their study had attenuation values less than that of renal parenchyma

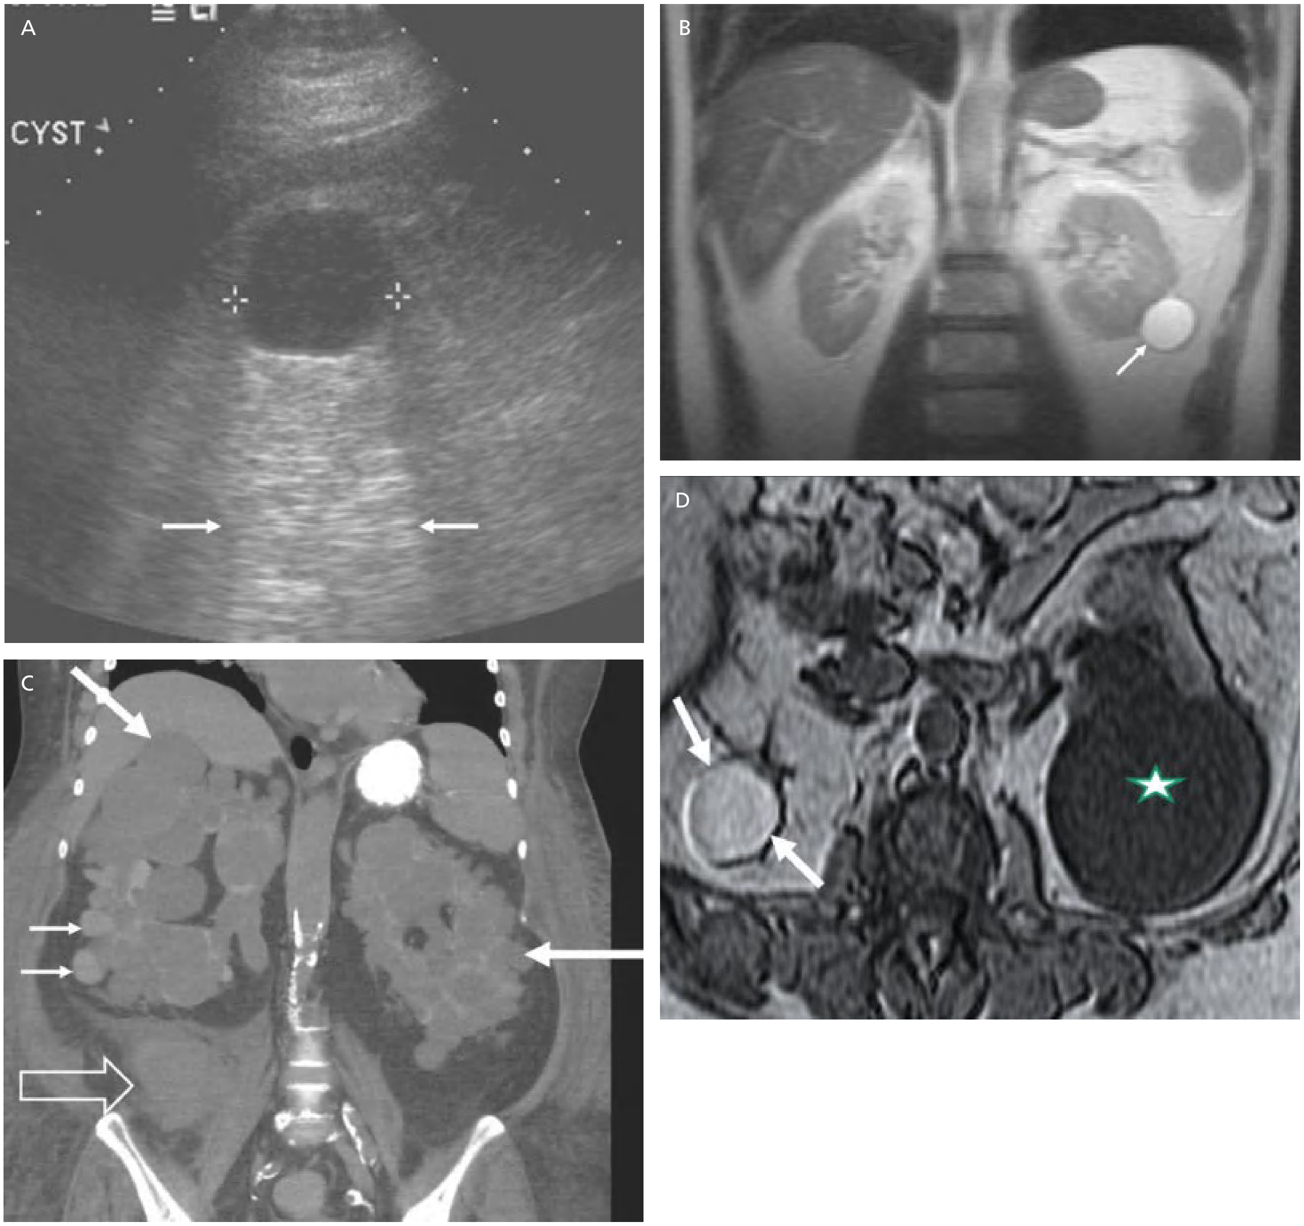

Figure 109.2 Bosniak type II renal cyst. (A) Transverse sonogram shows a well-marginated cystic structure (cursor) with fine, low level internal echoes. Note the acoustic enhancement (arrows) posterior to the cyst. (B) Coronal T1-weighted MR image shows a hyperintense cyst (arrow) indicating the presence of hemorrhage and/or mucin. (C) Coronal unenhanced CT scan in a patient with adult polycystic kidney disease demonstrates multiple simple (type I) (large solid arrows) and hyperdense (type II) (small solid arrows) renal cysts. The high attenuation within the cysts is due to hemorrhage. There is a renal transplant (open arrow) in the right iliac fossa with surrounding hemorrhage. (D) Axial T1-weighted image reveals a hyperintense hemorrhagic (type II) right renal cyst (solid arrows) and a hypointense left simple (type I) renal cyst (star).

(20–30 HU) and were often heterogeneous in attenuation. High attenuation renal cysts can in many cases be differentiated from RCC on unenhanced CT [16, 42, 43].

Category IIF lesions

These lesions are likely benign but require a period of observation or follow-up (the F stands for follow-up) to prove their benignity (Figure 109.3). These lesions may contain an increased number of septa or have minimal septal or mural thickening. Category IIF lesions may contain thick, irregular or nodular calcifications. When a high-attenuation lesion is completely intrarenal, the smoothness of its wall cannot be assessed. Accordingly, completely intrarenal high-attenuation lesions, as well as lesions greater than 3 cm in diameter, are included in

this category. These lesions may also have a slightly indistinct interface with the adjacent renal parenchyma [34–38].

These lesions should be reimaged with CT or MRI in 6 months and then annually or every other year for 5 years. Stability over time suggests these lesions are benign, recognizing that some malignant lesions can grow slowly and that cysts can enlarge. Therefore, on follow-up imaging their morphologic characteristics must be evaluated in addition to their size. If there is any increase in the thickness or in the irregularity of the wall or septa, surgical exploration is indicated. MRI can be particularly useful in evaluating hemorrhagic cystic renal masses and for the presence of septal or mural enhancement. The introduction of the IIF category in 1993 has prevented unnecessary surgery in large numbers of patients [34–38].

Category III lesions

These are truly indeterminate lesions that cannot be diagnosed accurately as benign or malignant based on their imaging appearance. They contain thick walls or thick septa that demonstrate measurable enhancement (Figure 109.4). They may contain more extensive, thickened, and irregular calcifications. At pathology, these lesions are multilocular cysts, infected or hemorrhagic cysts, multilocular cystic nephromas, or cystic RCCs. The risk of malignancy in this group has been reported to range up to 59%. Since significant numbers of patients with Bosniak type III lesions undergo surgery for ultimately benign disease, some have advocated biopsy in this patient cohort [1, 4, 20].

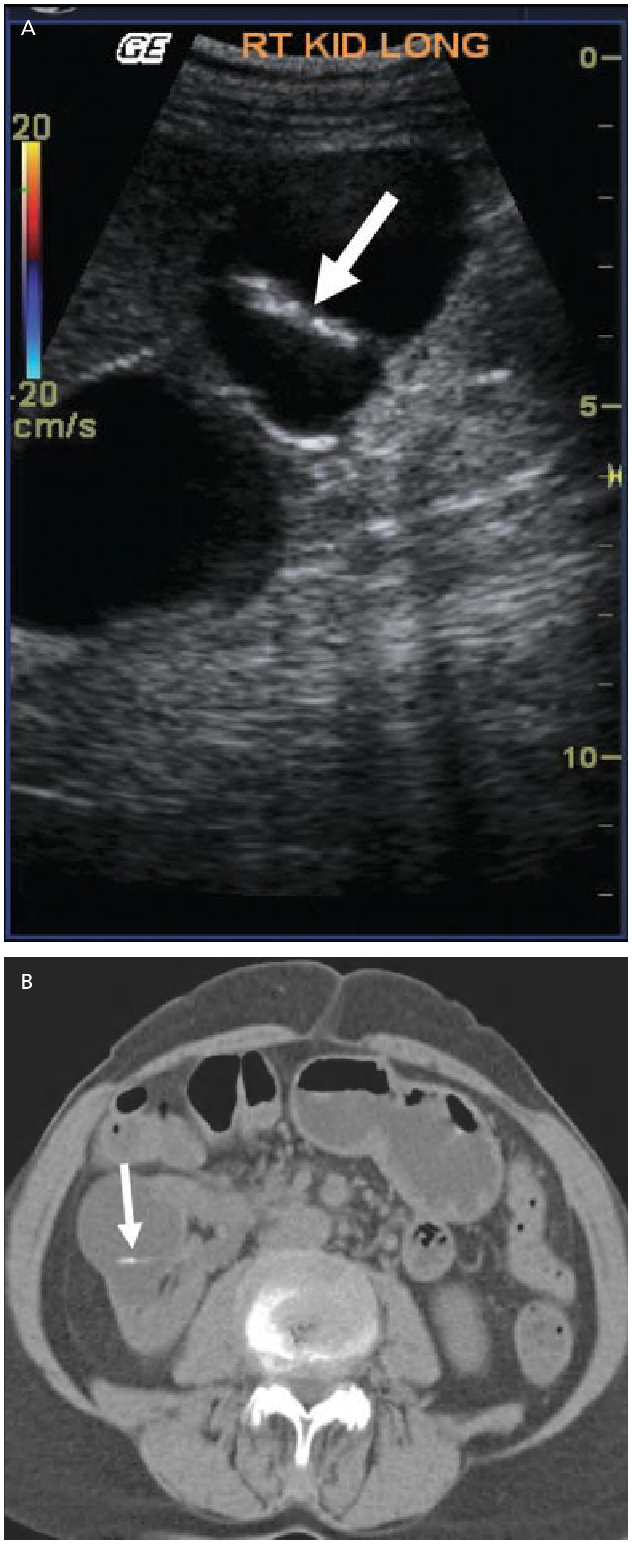

Figure 109.3 Bosniak type IIF renal cyst. (A) Longitudinal sonogram shows minimal thickening and calcification of a septation (arrow) in a patient with right renal cysts. (B) The calcification (arrow) is better appreciated on this transverse unenhanced CT scan. This lesion otherwise fulfills the imaging criteria for a simple cyst.

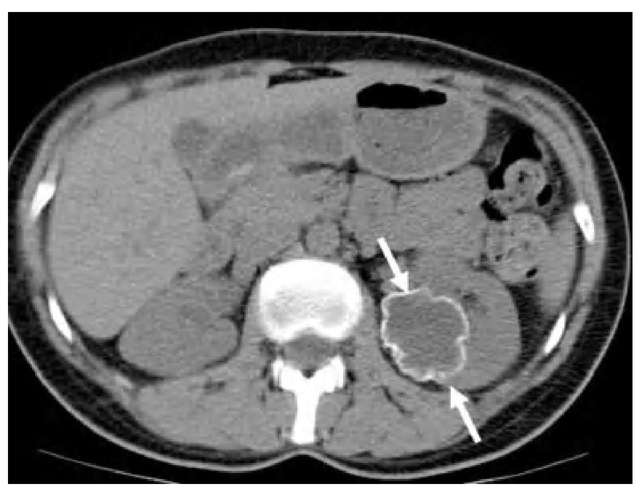

Figure 109.4 Bosniak type III cystic renal lesion. Axial unenhanced CT scan shows thick, irregular calcification (arrows) associated with a low-density renal mass. This lesion proved to be a renal cell carcinoma.

Category IV lesions

These lesions are clearly malignant and require surgical removal. They may have findings similar to category III lesions, but also have enhancing soft tissue components adjacent to the wall or septa (Figure 109.5). These lesions are usually cystic clear-cell carcinomas (accounting for 4–15% of all RCCs), multilocular cystic RCCs, cystic nephromas, and mixed epithelial and stromal tumors [36–39].

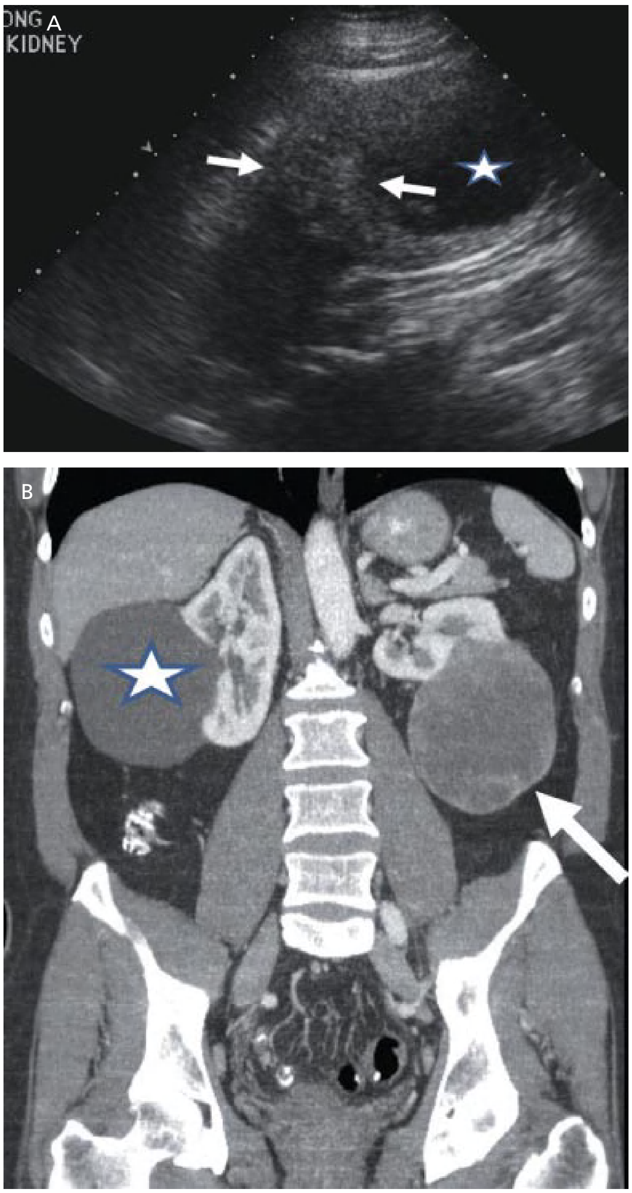

Figure 109.5 Bosniak type IV cystic renal lesion. (A) Longitudinal ultrasound of the left kidney shows a lower pole mass that has mural thickening superiorly (arrows) and a more cystic component inferiorly (star) (B) Coronal reformatted contrast-enhanced CT image shows mural and septal enhancement (arrow) of this mass. Note the Bosniak type I cyst at the lower pole of the right kidney (star).

Multilocular cystic nephromas

Multilocular cystic nephroma is a benign renal neoplasm that has a biphasic age and sex distribution. Two-thirds of multilocular cystic renal tumors occur in a predominately male pediatric population between the ages of 3 months and 2 years. Approximately one-third occur in a mostly female population, with a peak incidence in the fifth and sixth decades of life. Presenting symptoms depend on the age of the patient. Children typically present with a painless, progressively enlarging, palpable abdominal or flank mass that has a variable growth rate and may be discovered incidentally. Adults may have a variety of nonspecific signs and symptoms, including abdominal and flank pain, urinary tract infection, and hypertension. Microscopic or gross hematuria can occur in cysts in both adults and children. Variable degrees of obstruction of the renal collecting system can occur due to herniation of the tumor, which can lead to urinary tract infection.

Most adult patients are asymptomatic and these lesions are discovered incidentally. A complicated cystic lesion is typically identified on cross-sectional imaging (Figure 109.6) [36–39].

Benign solid renal masses

Most solid renal masses can be accurately characterized with cross-sectional imaging so that biopsy is not necessary [44, 45]. This is particularly true for AMLs (Figures 109.7 and 109.8) and RCCs, the two most common solid renal lesions in adults. Several pseudotumors can mimic solid renal lesions and must be excluded in order to avoid further evaluation or unnecessary surgery. Occasionally, a prominent column of Bertin, a dromedary hump, or persistent fetal renal lobulation can simulate a renal mass on ultrasound, but these can usually be correctly diagnosed with CT or MRI. These pseudolesions have a similar contrast-enhancement profile to normal renal parenchyma. In the case of persistent renal fetal lobulation, a normal renal pyramid is present within the center of the bulging portion of renal parenchyma.

Benign lesions that can simulate a renal neoplasm include focal acute pyelonephritis [46], renal abscess (Figure 109.9) [47], renal hematoma (Figure 109.10) [48, 49], focal xanthogranulomatous pyelonephritis (XPG) [50, 51], arteriovenous malformations (AVMs) (Figure 109.11) [52–54], and acute focal infarction (Figure 109.12). Extremely rare entities such as extramedullary renal hematopoiesis, tuberculoma related to therapy for bladder cancer, and splenorenal fusion can also mimic a renal mass.

Often the clinical history or additional findings on CT can be useful in making the correct diagnosis. For example, stranding in the adjacent perinephric fat

Figure 109.6 Multilocular cystic nephroma: CT features. (A) Axial and (B) coronal reformatted images disclose a multiseptated central cystic mass (arrows) involving the left renal pelvis.

should raise suspicion for acute pyelonephritis, although there are rare infiltrative renal tumors such as medullary RCC that can demonstrate this finding. In the case of focal pyelonephritis, there is a wedge-shaped area of heterogeneous hypoattenuation with no well-defined wall and no bulge on the renal surface, features that help distinguish it from RCC. If there is still a question about the nature of the mass, a follow-up scan showing healing and resolution can be helpful [46, 47].

AVMs can be intraparenchymal (see Figure 109.11) or in the renal sinus, but observing that the mass enhances to the same degree as the renal artery should be the clue to the correct diagnosis on CT and MRI. The feeding renal artery to the AVM is often enlarged as well. On gray-scale ultrasound an AVM appears as an anechoic structure that fills with color on color Doppler sonography. On noncontrast MRI scans, AVMs manifest as intralesional flow voids that show early enhancement, abnormal tortuous vessels, and an early draining vein following the intravenous administration of contrast [52–54].

Focal XGP can be difficult to distinguish from an RCC, but the presence of a staghorn calculus, which occurs in 70% of cases, is a helpful clue. There may be low attenuation within the associated collecting system mass due to the presence of lipid-laden macrophages. This disorder typically occurs in diabetic patients [50, 51].

When renal hematomas (see Figure 109.10) occur in the setting of trauma, the diagnosis is usually straightforward. However, renal hematomas can also occur spontaneously in patients who are anticoagulated, or have a coagulopathy or vasculitis. Typically, radiologists are not privy to this information to assist in the diagnosis. On noncontrast CT images, the hematoma may be hyperdense and there should be no contrast enhancement. Occasionally, active extravasation of contrast may be visualized. Hematomas are more easily diagnosed with MRI because of the typical signal characteristics of blood.

Subepithelial renal pelvic hematomas (Antopol–Goldman lesions) are a rare cause of a heterogeneously dense or hyperdense mass in the renal pelvis. They do not show contrast enhancement and may cause worrisome extrinsic compression on the renal collecting system. These lesions are often confused with renal pelvic malignancies, and in most cases, patients have undergone nephrectomy for what was thought to be malignant disease [1].

Angiomyolipomas

AMLs are the most common benign mesenchymal renal neoplasms and are comprised of fat, smooth muscle, and vascular tissue [55–58]. They typically occur sporadically in middle-aged patients, and are four times more common in females than males. Tuberous sclerosis, an autosomal dominant disease, accounts for 10–20% of all individuals with AML. The lesions in tuberous sclerosis are seen in younger patients and with equal frequency in males and females. The lesions in the sporadic form are usually less than 5 cm in diameter; however, AMLs seen in tuberous sclerosis can be much larger and are often multiple and bilateral [59]. Although benign, AMLs often increase in size over time and larger tumors have a propensity to bleed (see Figure 109.8). AMLs have a greater tendency to grow when they are multiple.

The imaging appearance varies according to the proportions of fat, muscle, and blood vessels. Since 95% of AMLs contain macroscopic fat (see Figures 109.7 and 109.8), the diagnosis can usually be made with

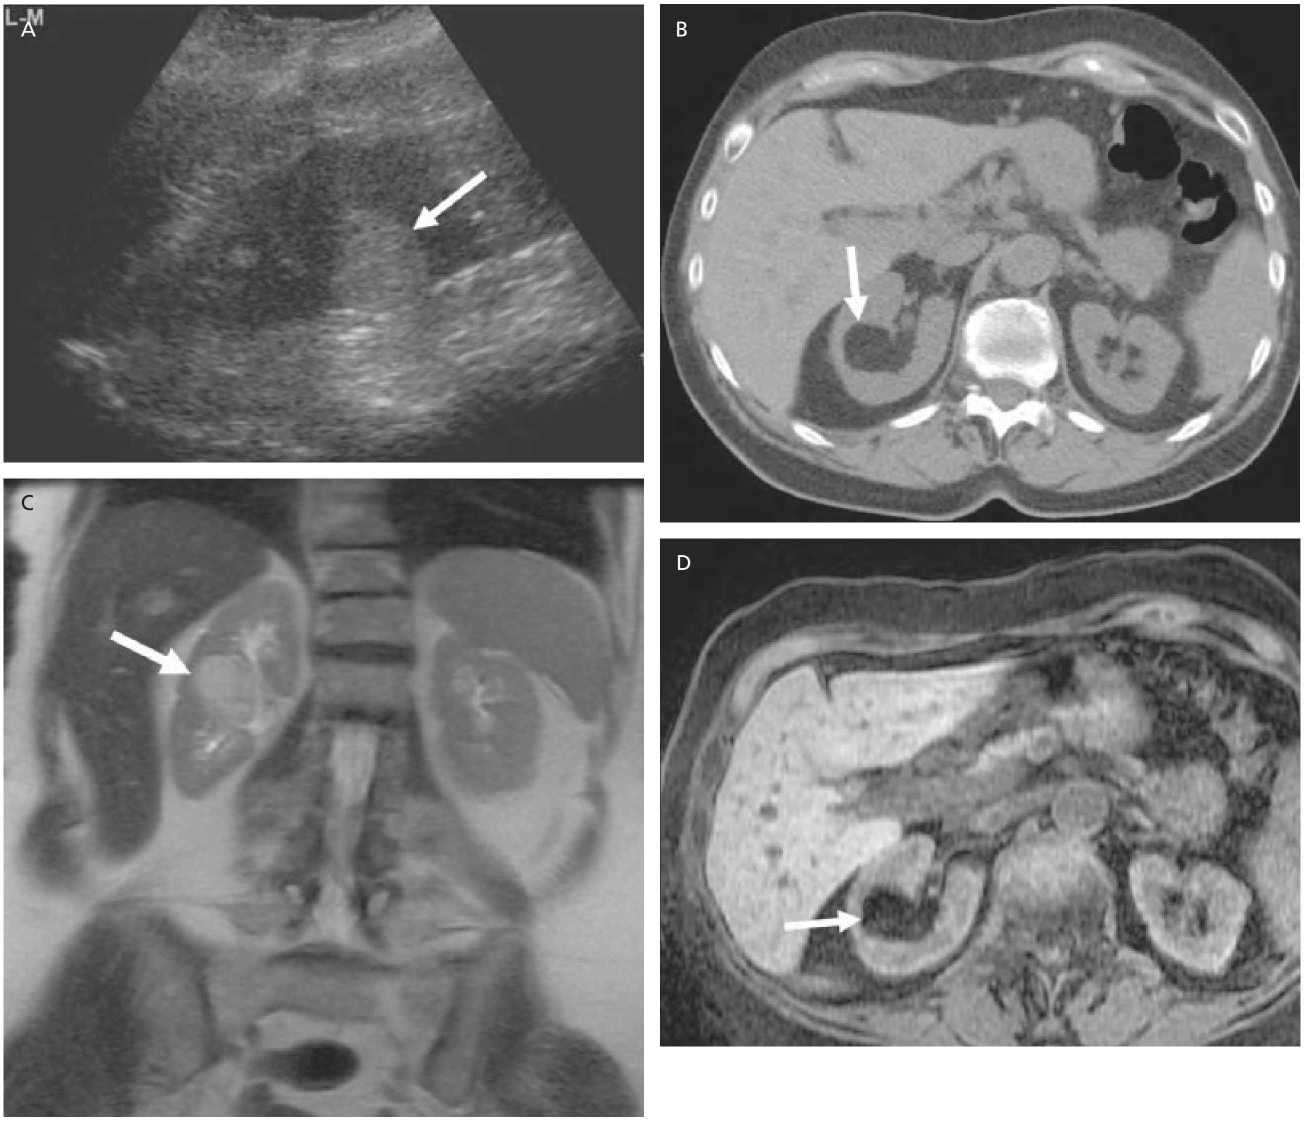

Figure 109.7 Renal angiomyolipoma: imaging features. (A) Longitudinal sonogram demonstrates a well-marginated uniformly hyperechoic renal mass (arrow). (B) Axial unenhanced CT scan shows a well-circumscribed, fat-containing right renal mass (arrow), with a density of –85 HU. (C) This mass is hyperintense on this T1-weighted coronal MR image. (D) This lesion (arrow) shows signal drop out on this axial, fat-suppressed MR image.

confidence on unenhanced CT when there are one or more regions of fat in a noncalcified renal lesion. They are typically well marginated, cortical in location, and predominantly fatty lesions with heterogeneous regions of soft tissue attenuation interspersed throughout the mass. Although the soft tissue components of the mass may enhance with intravenous contrast, this is not a dominant feature of most AMLs [55–59].

Sonographically, small AMLs appear as uniformly hyperechoic lesions (see Figure 109.7). Unfortunately, this sonographic appearance is also seen in 32% of small (<3 cm) RCCs. Echogenic carcinomas are more likely to have a hypoechoic rim and cystic areas, while AMLs are more likely to demonstrate acoustic shadowing and no hypoechoic rim. These findings are not sufficiently sensitive or specific to confidently make the diagnosis, so CT or MR is required for further evaluation. Larger AMLs are more complex on ultrasound and difficult to diagnose. On MRI (see Figure 109.7), most AMLs can be readily characterized with fat-suppression techniques, including combined T1-weighted regular (in-phase) and fat-suppressed images or combined T1-weighted in-phase and out-of-phase spoiled gradient-echo sequences [55–59].

The absence of a complete elastin layer in the blood vessels of AMLs predisposes these lesions to aneurysm formation and hemorrhage. The aneurysms, commonly seen on angiography, may not be appreciated on cross-

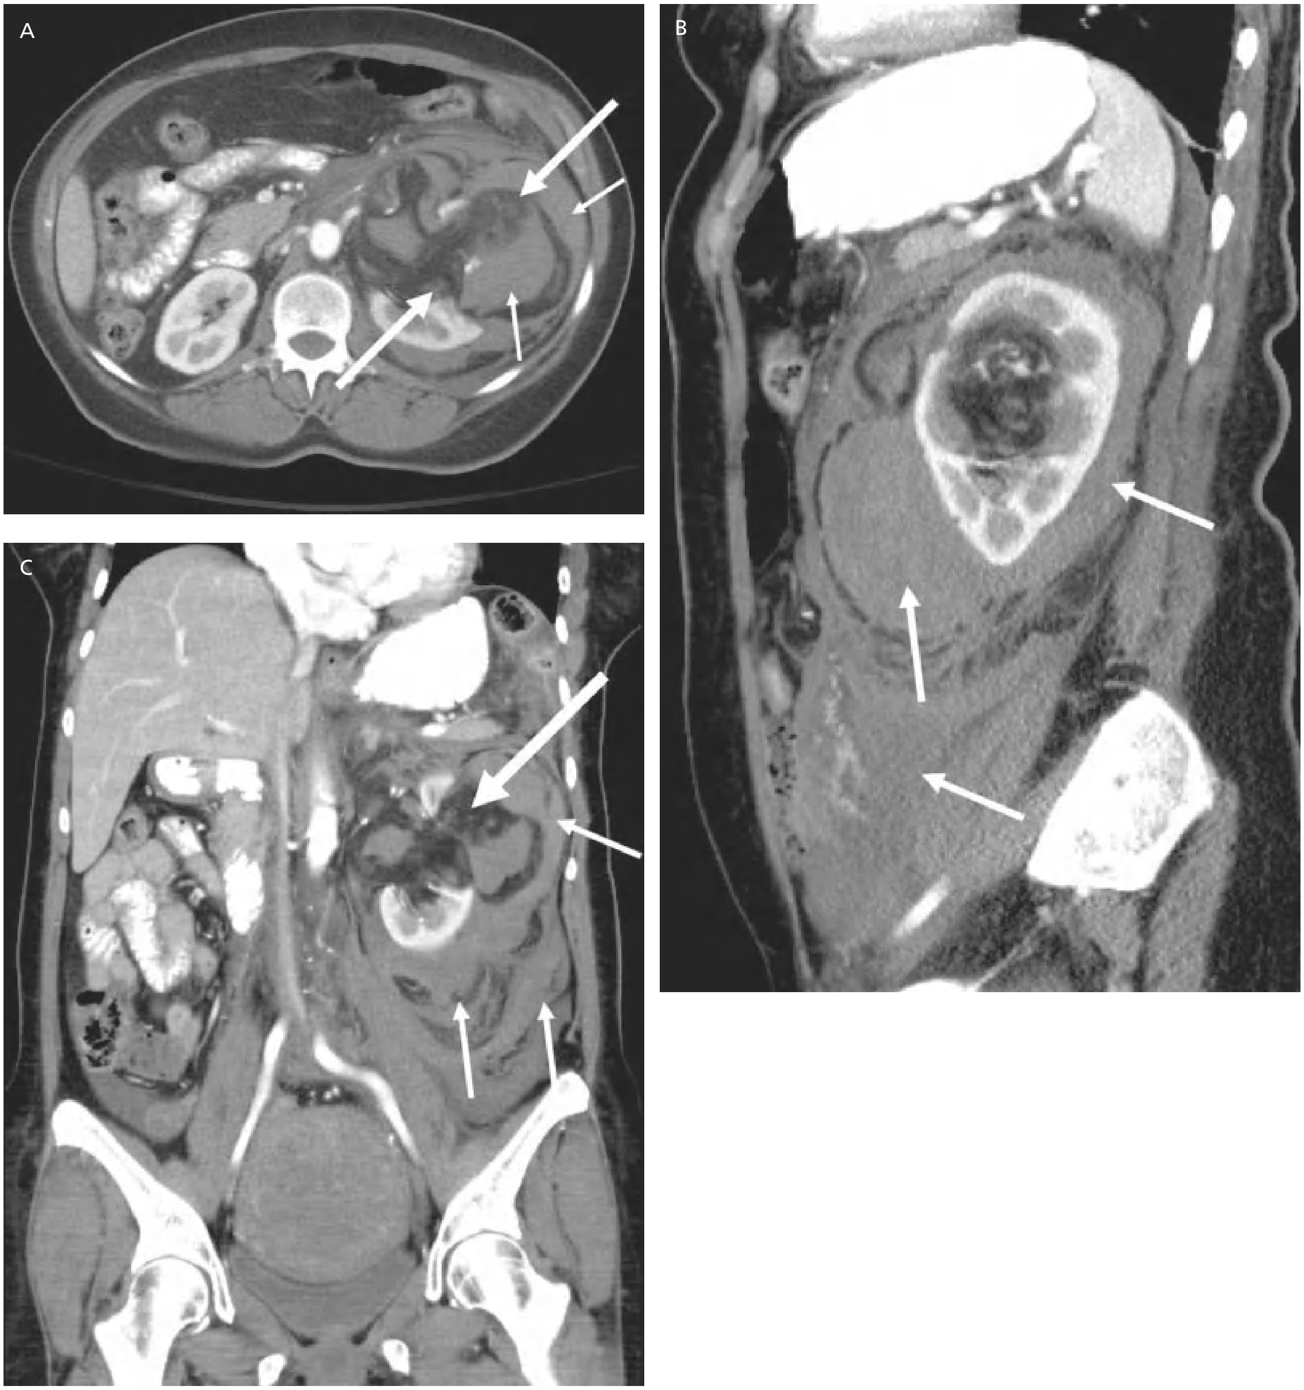

Figure 109.8 Hemorrhagic angiomyolipoma: CT features. (A) Axial, (B) sagittal, and (C) coronal CT images show a large fat-containing angiomyolipoma (large arrows) associated with a large renal and perirenal hematoma (small arrows).

sectional imaging studies. Hemorrhage is not uncommon. When the lesions bleed, they can present a diagnostic dilemma as the fat may be masked by the hemorrhage. Lesions larger than 3.5–4.0 cm in diameter are believed to have an increased risk of hemorrhage, and are often electively resected with nephron-sparing surgery. In patients with high surgical risk and those with tuberous sclerosis who may have limited renal reserve, selective arterial embolization can be performed [55–59].

There have been reported cases of macroscopic fat in clear-cell RCCs. In these cases, extensive calcification is also present in the mass. Since calcifications in AMLs and fat without calcifications in RCCs are both extremely rare, a fatty noncalcified renal mass is considered diagnostic of AML. Other fat-containing renal lesions that

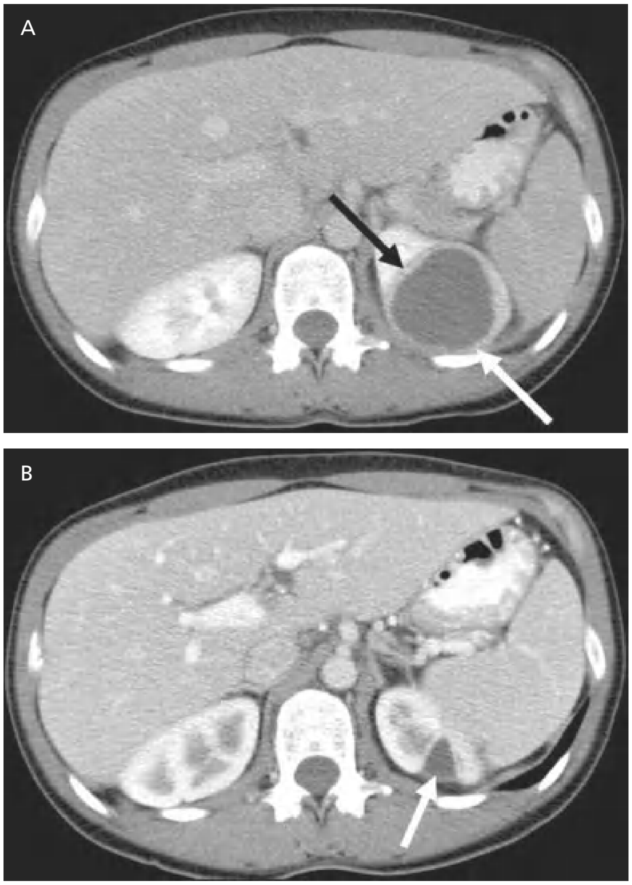

Figure 109.9 Renal abscess causing a low-density renal mass. (A) Transverse contrast-enhanced CT scan shows a thick-walled low-density mass (arrows) at the upper pole of the left kidney. (B) Scan obtained 3 months after the completion of antibiotic therapy shows a much smaller residual renal mass (arrow).

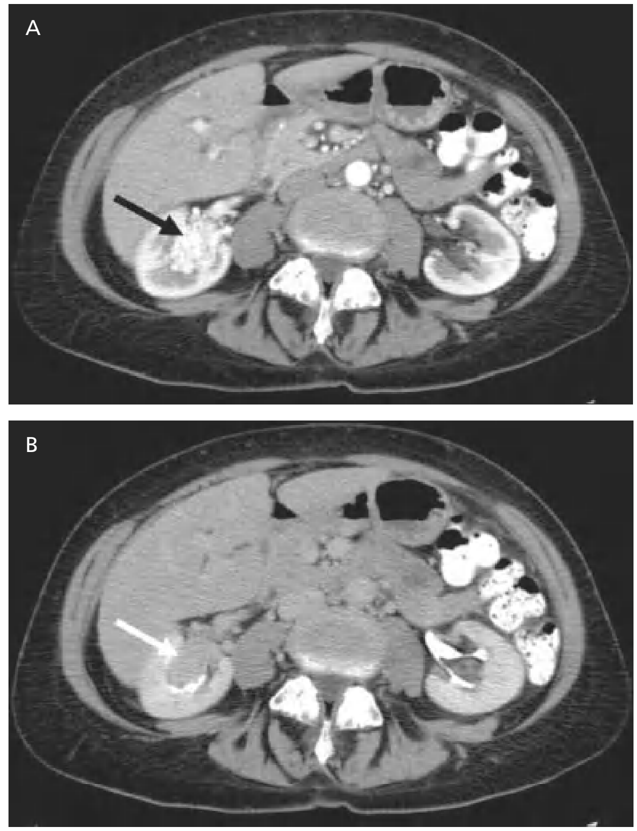

Figure 109.11 Arteriovenous malformation simulating a renal pelvic mass. (A) Axial CT scan obtained during the corticomedullary phase of enhancement shows multiple tubular enhancing structures (arrow) in the right renal pelvis. (B) On the excretory phase images, they simulate a right renal pelvic tumor (arrow). Parapelvic cysts are present in the left kidney.

are extremely rare and are not usually included in the differential diagnosis are lipoma, liposarcoma and, even more rarely, oncocytomas [55–59].

Lipid-poor AMLs (approximately 5%) pose a diagnostic problem in that they appear as solid enhancing masses that have been considered indistinguishable from RCCs based on imaging findings. However, recent studies have suggested that a small (<3 cm) hyperattenuating lesion on noncontrast CT which demonstrates homogeneous enhancement has a strong likelihood of being a benign lesion [55–59]. This lesion can be further evaluated with MRI to assess for microscopic fat. Percutaneous biopsy can also be performed on these lesions.

Oncocytoma

Oncocytomas are benign renal cell neoplasms that account for approximately 5% of adult renal epithelial

Figure 109.12 Renal infarct simulating a hypovascular renal mass. (A) Axial and (B) coronal reformatted contrast-enhanced CT images show a wedge-shaped region of markedly decreased enhancement (arrows) along the lateral aspect of the interpolar region of the left kidney.

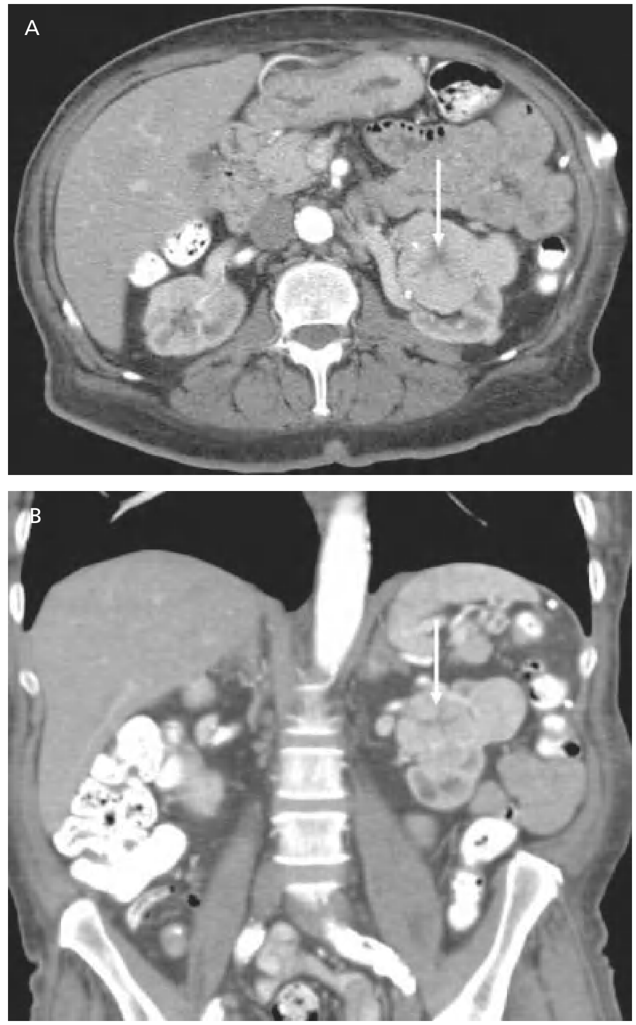

Figure 109.13 Renal oncocytomas: CT features. Multiple renal masses are identified on (A) axial and (B) coronal contrast-enhanced CT scans. Note the spoke-wheel pattern (arrow) of enhancement.

neoplasms in surgical series. They are more common in men than in women, and their peak incidence is in the seventh decade. There are some imaging features that suggest the diagnosis of oncocytoma, including homogenous enhancement and a central stellate fibrotic nonenhancing scar in approximately one-third of cases. The scar can appear high signal on T2- weighted sequences. Classic CT (Figure 109.13), MRI, and angiographic findings for oncocytoma including a spoke-wheel pattern, a homogeneous tumor blush, and a sharp, smooth rim. Oncocytomas typically do not have perinephric stranding. Unfortunately, the imaging features of oncocytomas demonstrate considerable overlap with those of RCCs, particularly the clear-cell subtype, and therefore cannot be reliably used for diagnosis. Indeed, oncocytomas often manifest as a complex hypervascular mass that is sometimes associated with adjacent neovascularity and perinephric stranding, findings that are worrisome for a clear-cell carcinoma. Advances in immunocytochemical analysis and cytogenetics may be helpful in distinguishing oncocytoma from RCC in the future, but at this time oncocytomas cannot be reliably diagnosed with percutaneous biopsy, and they typically are surgically resected [60–62].

Other benign solid renal masses

There are other benign solid renal lesions that cannot be reliably distinguished from RCCs, though some have imaging features that may suggest the diagnosis.

Papillary adenomas and renomedullary interstitial cell tumors are less than 5 mm in diameter and are common at autopsy [4]. Metanephric adenomas are usually solid and hyperattenuating on noncontrast CT and 20% contain calcification. Hemangiomas and lymphangiomas typically arise in the renal pyramids or pelvis. Leiomyomas commonly appear as well-circumscribed homogeneous exophytic solid masses that demonstrate uniform enhancement with intravenous contrast. Juxtaglomerular cell neoplasm (reninoma) is an endocrine tumor, which typically occurs in the second or third decades of life, and is twice as common in females as in males. Patients present with hypertension and hypokalemia. These lesions typically appear as well-circumscribed cortical tumors of less than 3 cm in diameter. Despite the fact that they are such vascular lesions pathologically, they appear hypovascular on contrast CT, possibly due to renin-induced vasoconstriction [4]. Mixed epithelial and stromal tumors consist of solid and cystic areas that may herniate into the renal pelvis. The observation of some of these features may be sufficient to raise the possibility of a benign lesion and in some cases biopsy should be considered rather than immediate surgery [4].

Renal cell carcinoma

RCC is the eighth most common malignancy and accounts for 2–3% of new cancers in the USA. RCC typically presents in the fifth to seventh decade of life, and is two to three times more common in men than in women, and slightly more common in blacks than in whites. The tumors are usually solitary, but can be multifocal in 6–25%. In patients with certain genetic conditions, such as von Hippel-Lindau disease (Figure 109.14), hereditary papillary renal cancer (Figure 109.15), and possibly tuberous sclerosis, multifocality is common. Indeed, multifocal tumors are seen in 87% of patients with von Hippel–Lindau disease [63–65]. RCC is also more common in patients with acquired cystic renal disease, with a three to six times increased risk in patients on long-term dialysis [63, 64]. Because RCCs may be multifocal or bilateral, both kidneys must be scrutinized when staging the lesion prior to surgical or percutaneous intervention.

In recent years, the incidence of RCC has increased due to several factors. In large part this is secondary to the increased incidental detection on imaging studies. Now nearly two-thirds of renal neoplasms are found incidentally compared to approximately 10% in the early 1970s. There has also been an increased rate of survival in patients with RCC primarily due to the fact that these lesions are found when small in asymptomatic individuals. There is some evidence suggesting that asymptomatic tumors are smaller and of lower grade and earlier stage than symptomatic lesions. The overall 5-year survival rate is approximately 85% for incidentally detected tumors compared to 53% in symptomatic individuals [63, 64]. Therefore, radiologists have

Figure 109.14 Synchronous renal cell carcinoma and mucinous adenocarcinoma of the pancreas in a patient with von Hippel–Lindau syndrome. (A) Axial and (B) coronal reformatted CT images show a clear-cell renal cell carcinoma in the upper pole of the right kidney (solid arrows) and calcified and noncalcified cystic lesions (open arrow) in the pancreatic body and tail. The calcified cystic lesion was a mucinous cystadenocarcinoma.

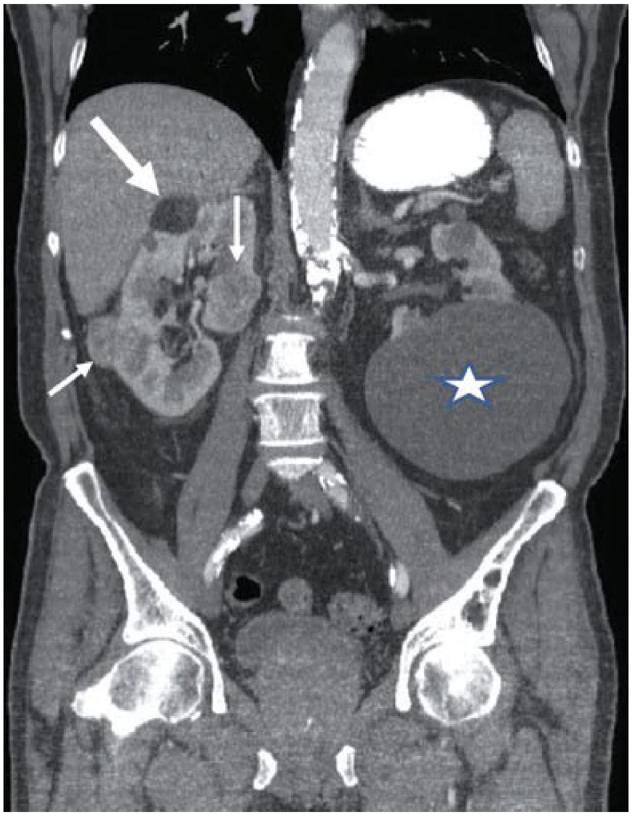

Figure 109.15 Hereditary papillary renal cancer. Coronal reformatted contrast-enhanced CT image shows synchronous hypervascular neoplasms in the right kidney (small arrows). Note the angiomyolipoma (large arrow) and the large left benign renal cyst (star).

played and continue to play a significant role in finding early cancers and improving patient survival.

According to the 1997 Heidelberg classification, the most common RCC histologic subtypes are: clear-cell adenocarcinoma (65–75%), papillary adenocarcinoma (15%), chromophobe (5%), collecting duct (1%), and unclassified carcinomas (4%). Clear-cell RCC, also known as conventional RCC, has a much greater malignant potential than papillary and chromophobe RCCs. Since the prognosis varies among the subtypes of RCC (Table 109.2), being able to distinguish these with imaging can have important clinical implications in the management of certain groups of patients [66–72].

Clear-cell RCC is the most vascular type of all malignant renal cortical tumors, as shown by its greater degree of enhancement after administration of intravenous contrast. It most commonly presents with a mixed enhancement pattern of both hypervascular soft tissue components and low attenuation areas that correspond to necrotic or cystic changes. Kim *et al*. showed that an increase in attenuation of 84 HU in the corticomedullary phase differentiates clear-cell from nonclear-cell

Table 109.2 Histologic subtypes of renal cell carcinoma.

Clear-cell renal cell carcinoma
Multilocular clear-cell carcinoma
Papillary renal cell carcinoma

Collecting duct carcinoma
Translocation carcinomas
Renal cell carcinoma associated with neuroblastoma
Mucinous tubular and spindle cell carcinoma
Renal cell carcinoma unclassified

tumors with a sensitivity of 74% and a specificity of 100% [73].

Papillary RCC, on the other hand, demonstrates a low degree of enhancement relative to renal cortical enhancement in either a homogenous pattern or with low-level peripheral enhancement. A low tumor-to-aorta enhancement ratio or tumor-to-normal renal parenchyma enhancement ratio is highly indicative of papillary RCC [74, 75].

Chromophobe RCCs are more variable in their degree and pattern of enhancement. Renal medullary carcinoma is a recently described malignant renal neoplasm occurring in patients with sickle cell anemia. It is centered in the medulla and microscopically exhibits a reticular, yolk sac or adenoid cystic appearance. This neoplasm exhibits aggressive behavior [66–72].

Generally, the presence of calcifications in a solid renal mass (Figure 109.16) suggests malignancy. Rarely, a malignant renal tumor may be diffusely calcified [76]. RCCs typically show de-enhancement of contrast of greater than 15 HU when comparing the corticomedullary phase to the excretory phase (Figure 109.17).

Staging renal cell carcinomas

RCCs spread via a number of pathways. They may invade locally, initially through the renal capsule into the adjacent perinephric fat. Upper pole tumors may invade the ipsilateral adrenal gland. More advanced tumors can involve the adjacent musculature or extend beyond Gerota's fascia to involve the liver, spleen, pancreas, duodenum, and colon. RCCs may invade the renal vein and propagate into the inferior vena cava and right atrium. Hematogenous metastases most commonly go to the lungs and bone. RCCs can also spread by lymphatic routes, beginning with the renal hilar lymph nodes and then the regional para-aortic lymph nodes [77–83].

Accurate preoperative staging of patients with RCC is of paramount importance in selecting the most suitable therapy, guiding surgical intervention, and assessing patient prognosis. The 40-year-old Robson

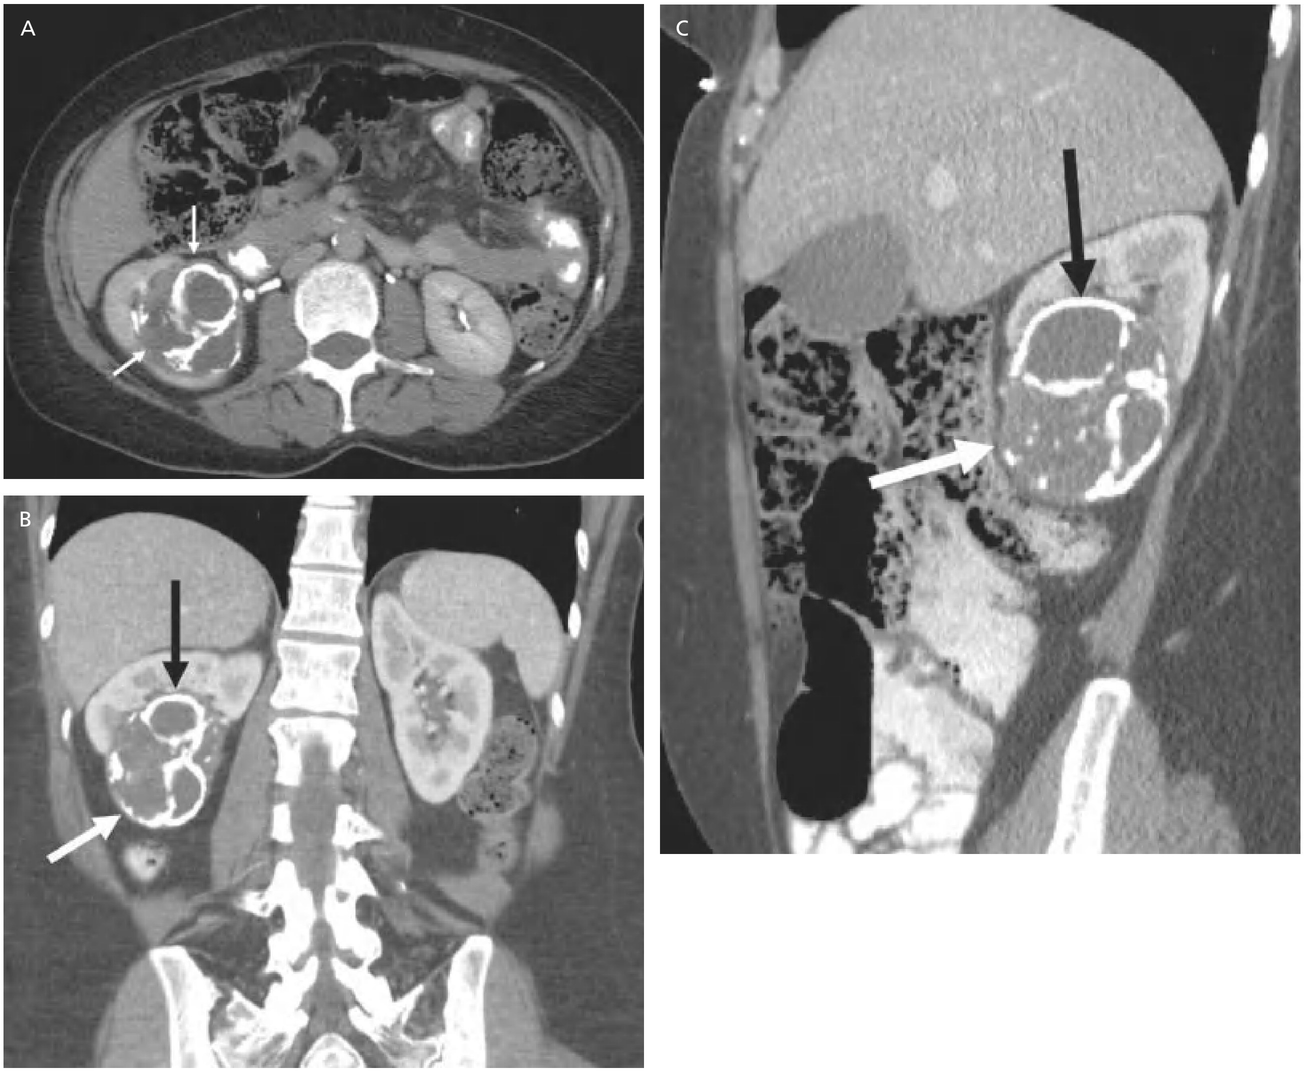

Figure 109.16 Calcified renal cell carcinoma. Calcified renal cell carcinoma (arrows) is seen at the lower pole of the right kidney on (A) axial, (B) coronal reformatted, and (C) sagittal reformatted contrast-enhanced CT images.

classification of RCC was replaced with the TNM staging system, developed in 2002 by the American Joint Committee on Cancer and the International Union Against Cancer (Tables 109.3 and 109.4), because the latter adapts more easily to changing patterns of diagnosis and therapy for RCC. Indeed, it appears that TNM staging is evolving with the advance of surgical techniques, and is now being challenged by the advent of new, minimally invasive treatment methods such as cryoablation and radiofrequency ablation. MDCT and MRI are superb for T staging of local tumor extent and M staging of distant metastasis. However, both imaging tests perform less well with N staging. Since FDG-PET appears to be unreliable in the detection of RCC and its metastases, research efforts should be directed at finding malignant adenopathy of RCC [77–83].

T staging

TNM classes T1 and T2 include all primary RCCs that are confined to the renal capsule (Figures 109.18 and 109.19). The TNM classification of 2002 distinguishes between T1a, which defines a RCC with a maximum diameter of 4 cm or less, and T1b, which defines a RCC whose maximum diameter is larger than 4 cm but smaller than 7 cm. Aside from potential differences in prognosis, the most likely reason for the migration of definitions for TNM classes T1 (now T1a and T1b) and T2 lies in the development of new surgical techniques of renal tumor resection [77–83].

It may be difficult to detect subtle invasion of RCC beyond the renal capsule on cross-sectional imaging (Figure 109.20). Anatomically, the true renal capsule rep-

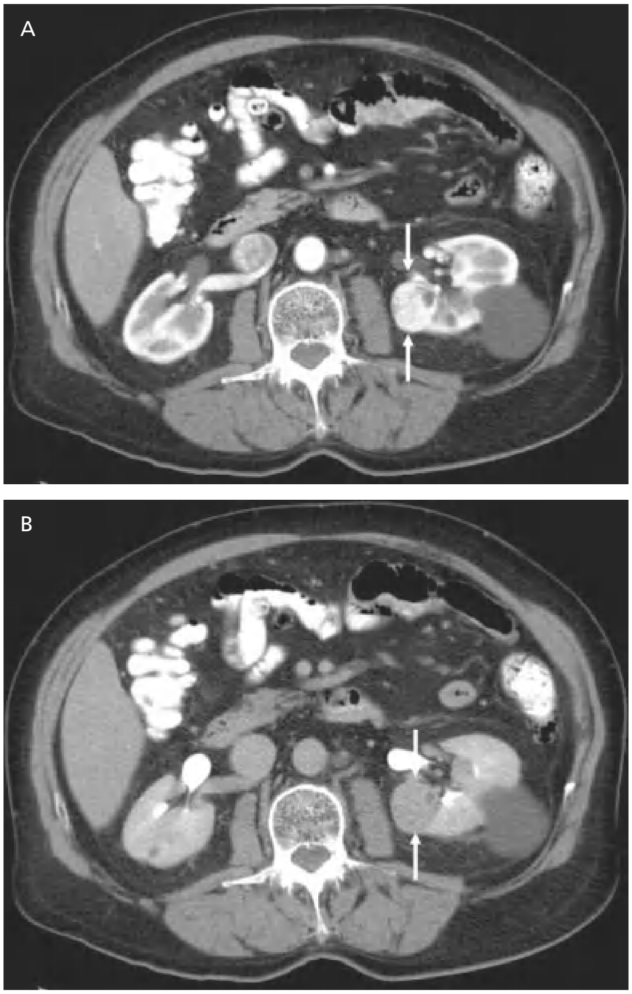

Figure 109.17 De-enhancement of renal cell carcinoma: CT findings. (A) Scan obtained during the cortical medullary phase shows an enhancing mass along the medial aspect of the left kidney (arrows). A simple renal cyst is also present. (B) 3-min delayed image shows that the contrast material has rapidly washed out of the tumor (arrow) and it is now hypodense relative to normal kidney. Bilateral simple renal cysts are present.

resents the fibrotic outer surface layer surrounding the renal parenchyma. This layer, however, is ill-defined or missing in the renal hilum. Pathologically, RCC induces reactions within the kidney and within the perirenal fat that may make it difficult to distinguish between the true renal capsule and the pseudocapsular structures [78, 79].

In terms of T3b and T3c lesions, both MRI and MDCT are comparable in assessing tumor invasion of the renal vein and extension into the inferior vena cava either below or above the diaphragm. Extension of RCC tumor thrombus above the diaphragm defines TNM class T3c (Figure 109.21) [78, 79].

T4 lesions are characterized by tumor extension through Gerota's fascia. This assessment may be difficult

Table 109.3 TNM staging system of renal cell carcinoma. (reproduced from Edge SB, Byrd DR, Compton CC, eds. AJCC Cancer Staging Manual. 7th ed. New York, NY: Springer, 2010).

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma *in situ*
T1	Confined to kidney T1a <4 cm T1b <7 cm
T2	Confined to kidney: > 7 cm
T3	Confined to Gerota's fascia T3A: extending to ipsilateral adrenal gland or perirenal fat T3b: extending to renal vein or inferior vena cava (IVC) below diaphragm T3c: extending to IVC above diaphragm
T4	Tumor extends beyond Gerota's fascia
*Regional lymph nodes (N)**	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, >2 cm but not >5 cm in greatest dimension; or multiple lymph nodes, none >5 cm in greatest dimension
N3	Metastasis in a lymph node, >5 cm in greatest dimension
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

*Laterality does not affect the N classification.

Table 109.4 TNM staging system of renal cell carcinoma (reproduced from Edge SB, Byrd DR, Compton CC, eds. AJCC Cancer Staging Manual. 7th ed. New York, NY: Springer, 2010).

Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0

Figure 109.18 T1a renal cell carcinoma. (A) Coronal reformatted CT image shows bilateral small lower pole renal tumors (arrows), which are limited by the renal fascia. (B) Axial T2-weighted MR image shows a complex renal neoplasm (arrow) confined by the renal fascia.

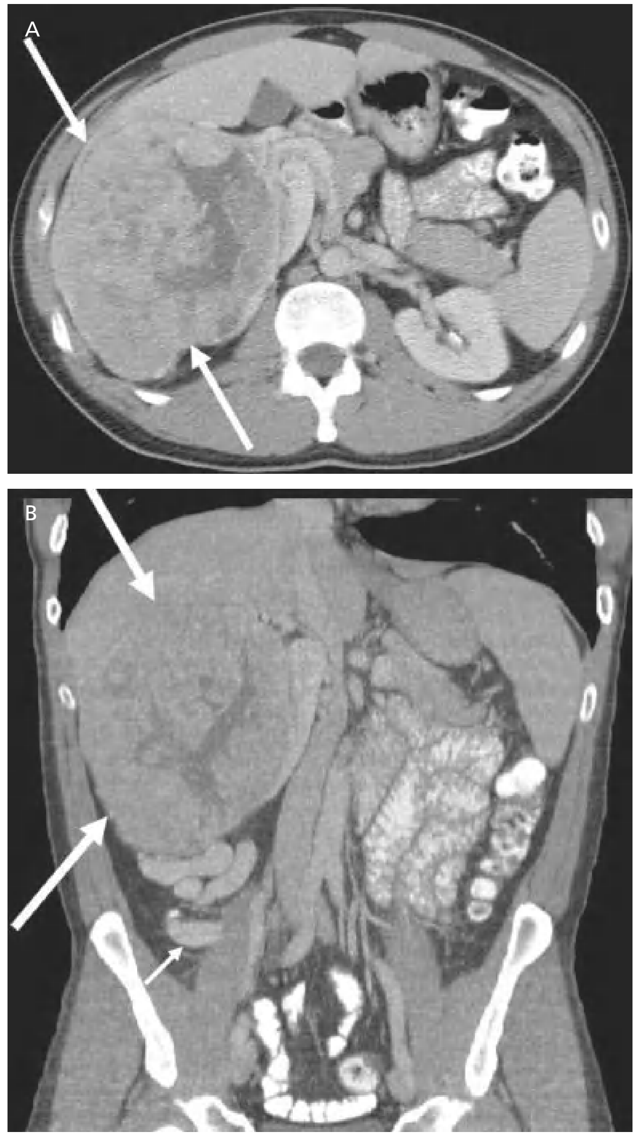

Figure 109.19 T2 renal cell carcinoma. (A) Axial CT image shows a 10.5-cm complex mass (arrows) replacing the majority of the right kidney. Despite its large size, the tumor was limited to the kidney at surgery. (B) Coronal reformatted CT image shows parasitization of retroperitoneal vessels (small arrow) feeding this large neoplasm (large arrows).

on cross-sectional imaging when the fascia is only minimally transgressed.

N staging

Involvement of regional lymph nodes has several different classifications in the TNM system (Tables 109.2 and 109.3). The most important lymph nodes to evaluate when staging patients with RCC include: nodes along the renal arteries and paracaval lymph nodes for right-sided tumors; para-aortic lymph nodes for left-sided tumors (see Figure 109.20B); and nodes located at the levels of the renal hilum or renal artery. Metastasis in regional lymph nodes without synchronous distant metastasis is found in 10–15% of patients with RCC [83, 84].

As with most neoplasms, the detection of lymph node metastases remains problematic in patients with RCC. Current MDCT and MRI criteria for suggesting adenopathy are lymph nodes that have a short-axis diameter of 1 cm or more and the presence of a prominent node that is more spherical rather than kidney shaped and has lost its hilar fat. Additionally, asymmetric grouping of three or more smaller lymph nodes may also be a sign of lymphatic tumor spread to the renal hilum. Further confounding the accuracy of cross-sectional imaging in detecting adenopathy is the fact

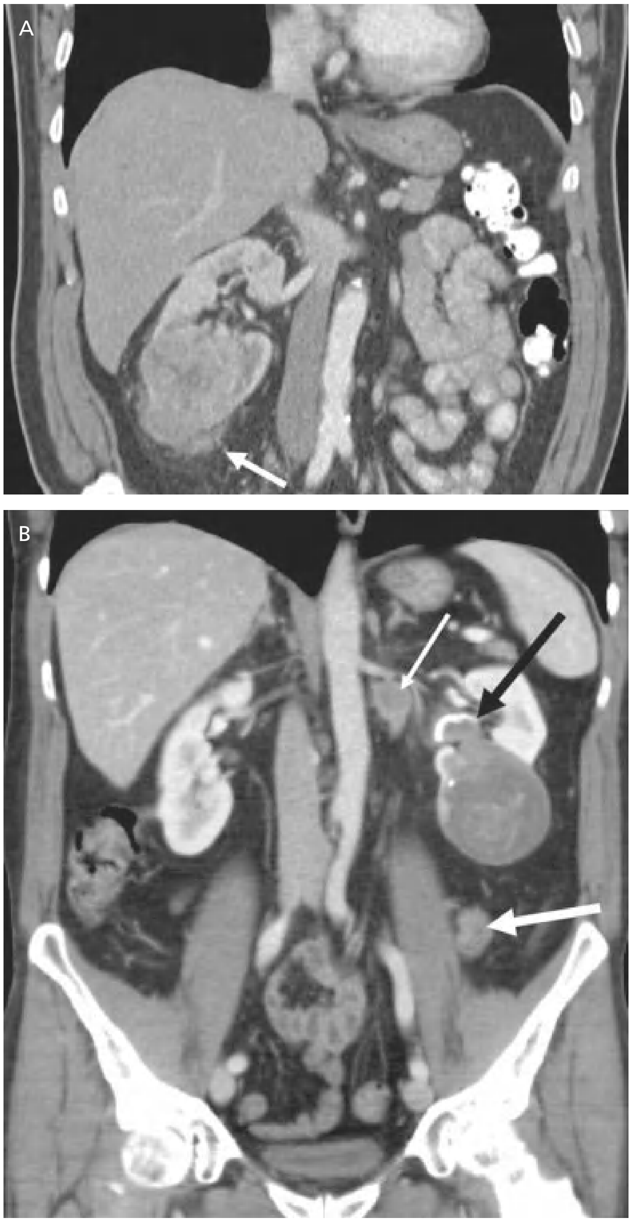

Figure 109.20 T3a, N2 renal cell carcinoma. (A) Coronal reformatted CT image depicts a 6.5-cm tumor extending through the right renal capsule (arrow) but confined by Gerota's fascia. (B) Coronal reformatted CT image in a different patient obtained during the excretory phase shows tumor invasion of the renal pelvis (black arrow). There is left renal hilar adenopathy (small white arrow) and a left paraspinous metastasis (large white arrow).

that more than 50% of enlarged regional lymph nodes exhibit only hyperplastic or inflammatory change pathologically [83, 84].

M staging

Distant metastases from RCC, M1 disease, includes all metastases that are either extranodal or involve nonregional lymph nodes. Metastases are most frequently found in the lung (31%) (Figure 109.22), bone (15%), brain (8%), and liver (5%). However, any other organ can be involved [29]. While metastatic RCC requires systemic therapy, surgical excision of the primary lesion appears to be an integral part of systemic therapy for metastatic RCC [85].

MDCT is the preferred means of M staging patients with RCC because it is superior to MRI in detecting pulmonary metastases. As stated above, FDG-PET at the present time appears too unreliable to recommend its routine use in the staging of RCC [86, 87].

Transitional cell carcinoma

Urothelial tumors of the renal calyces and pelvis account for approximately 7% of primary renal tumors and 5% of all urinary tract neoplasms. TCCs comprise 90% of pelvicalyceal tumors, with squamous cell carcinoma (which is radiologically indistinguishable from TCC) and adenocarcinomas accounting for 10% of these neoplasms. Patients with previous or current urothelial neoplasm of the bladder are at increased risk of developing TCC of the kidney. Indeed, upper tract urothelial tumors have similar risk factors, epidemiologic distribution, and pathologic features. Other risk factors include certain chemical exposures, nonsteroidal anti-inflammatory drug (NSAID) abuse, and tobacco use. Because of the multicentric nature of TCC, the urotheluium of the kidneys, ureters, and bladder must be assessed in its entirety prior to treatment to exclude synchronous lesions. During follow-up studies, metachronous tumors must be excluded as well [88–98].

The intravenous pyelogram (IVP) has traditionally been the initial screening examination for the detection of upper urinary tract neoplasms for patients with hematuria. The IVP, however, has been shown to miss 40% of upper tract cancers. This technique has been replaced by CTU using MDCT [88–98].

There are three general appearances of TCC on MDCT:

- *A small hypodense lesion in the renal collecting system* (Figure 109.23) demonstrating soft tissue attenuation (<40 HU). On noncontrast images, these tumors have a density of approximately 30 HU, which can be differentiated from urine (0–20 HU), blood clot (50–75 HU), and calculi (>100 HU). There is moderate enhancement with washout on delayed images following intravenous contrast administration, but the degree of enhancement is usually less than that seen in patients with RCC. Some 85% of these lesions are early-stage, superficial papillary neoplasms, that on the excretory phase of CTU appear as sessile filling defects within the high density contrast excreted into the renal collecting system. In more advanced cases, the tumor expands

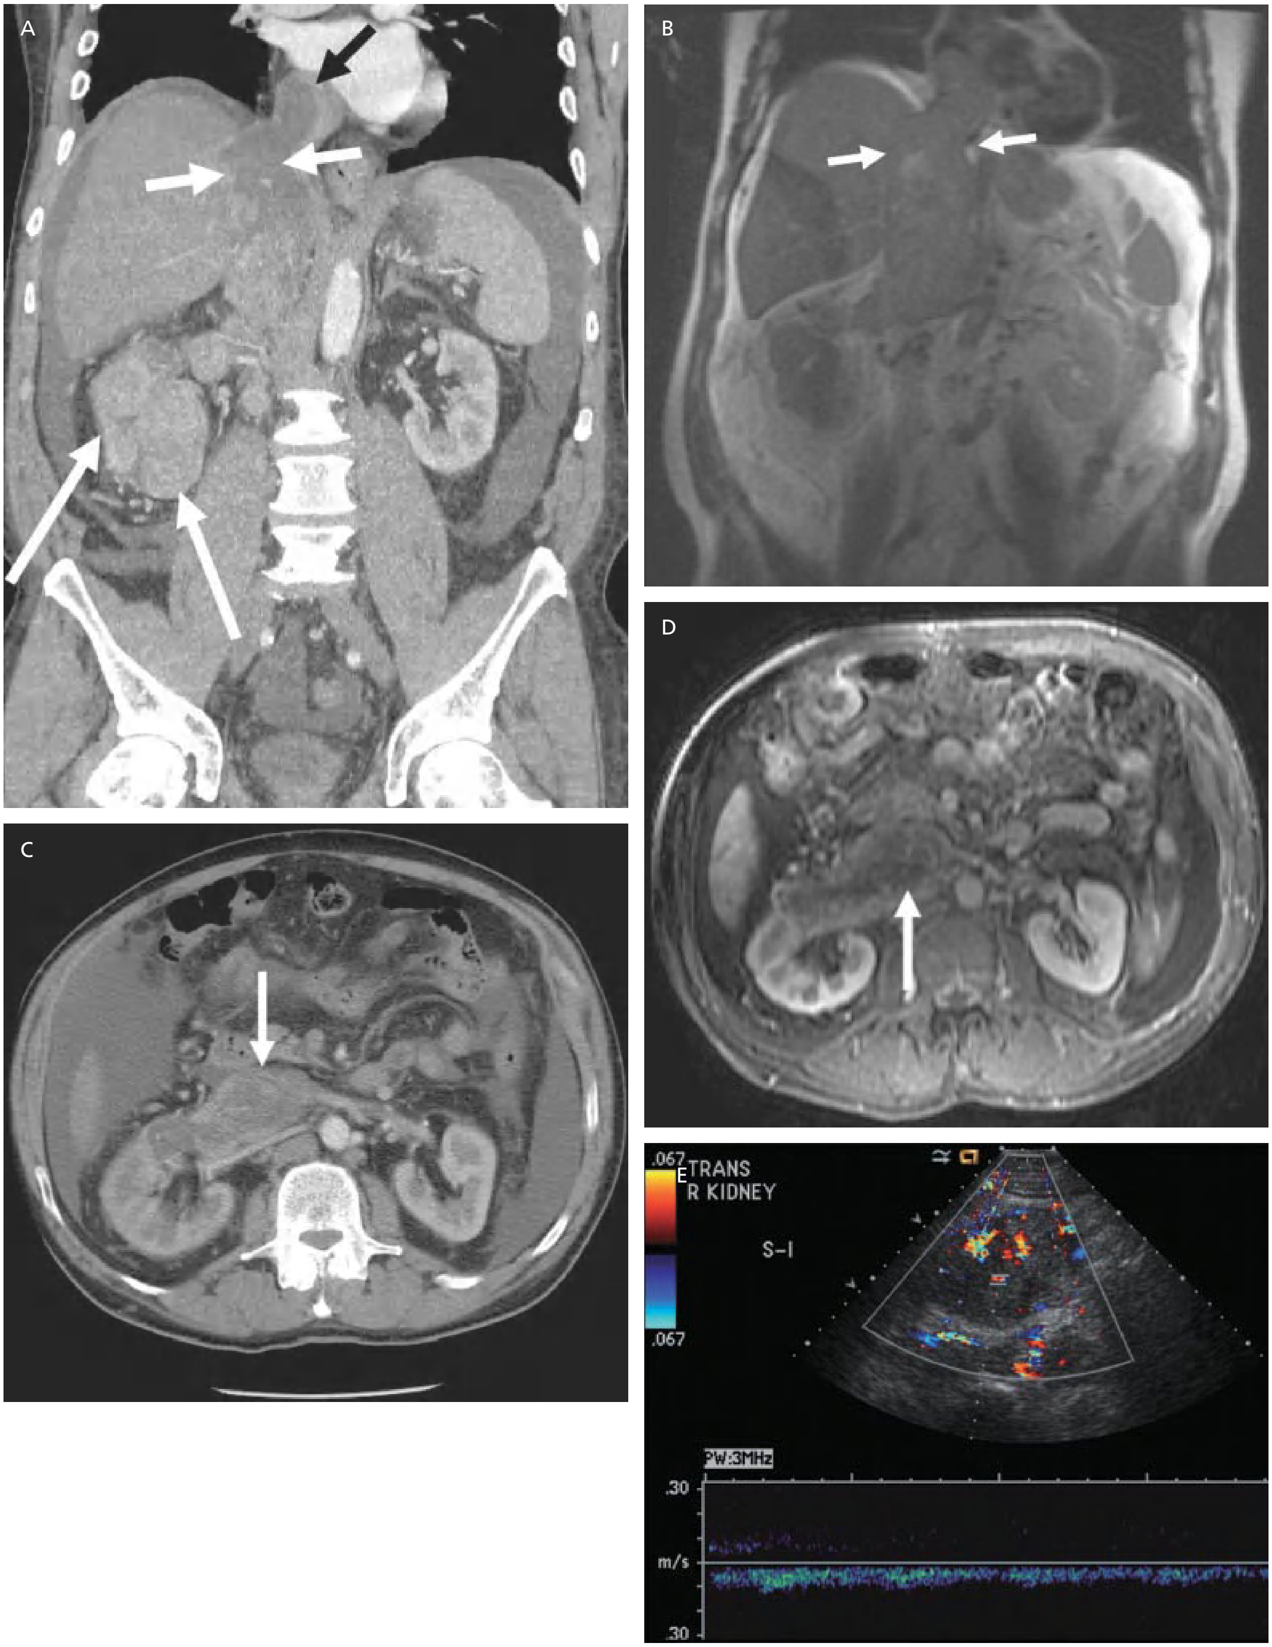

Figure 109.21 Stage T3c renal cell carcinoma. Coronal reformatted (A) CT and (B) MR images show a large right renal carcinoma (large white arrows) invading the left renal vein, inferior vena cava (small white arrows), and into the origin of the right atrium (black arrow). Axial (C) CT and (D) MR images better depict the invasion of the right renal vein (arrows) and inferior vena cava. (E) Color Doppler ultrasound shows flow within the tumor thrombus.

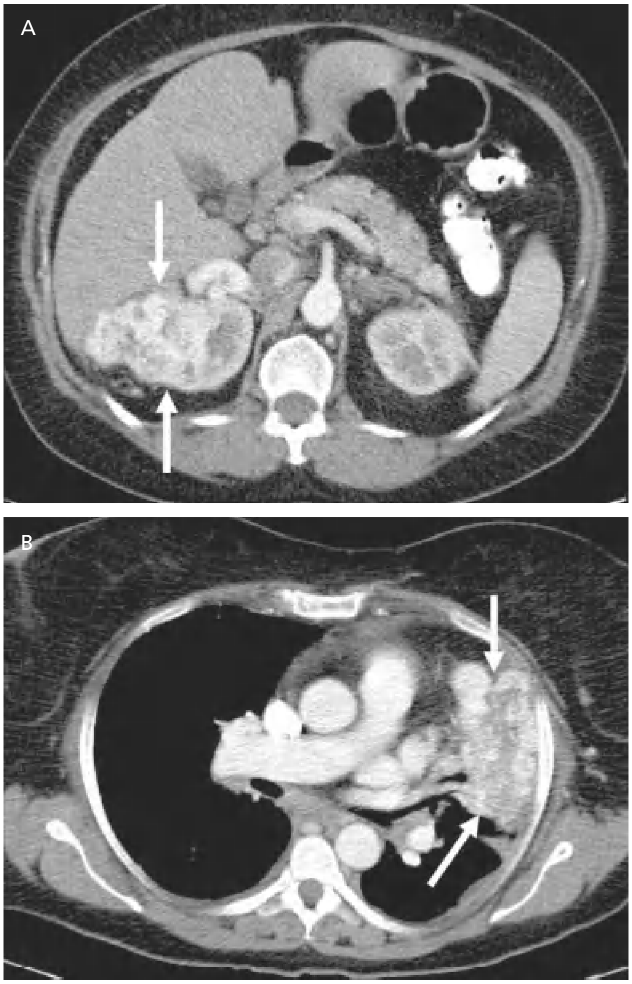

Figure 109.22 M1 renal cell carcinoma. (A) Axial, contrast-enhanced CT scan shows a hypervascular right renal mass (arrows). (B) Hypervascular metastasis (arrows) is present in the left chest and also invades the pleura.

the collecting system with compression of the renal sinus fat.

• *Mural thickening, usually symmetric, of the renal collecting system, resulting in circumferential narrowing of the lumen*. This may lead to focal calyceal obstruction. The thickened wall may demonstrate enhancement, but a thick enhancing wall can also be seen with infection or with inflammation related to calculi, hemorrhage, recent stent placement or removal, or other surgical manipulation. In some cases biopsy may be necessary to distinguish benign from malignant etiologies.

• *An infiltrating hypoenhancing renal mass* (Figure 109.24) with poorly defined margins. Because TCCs arise from the urothelium, they are more centrally located than most RCCs. A TCC may contain stippled calcification and may be large and necrotic. It may distort the normal renal architecture. When it expands the kidney, the renal contour is usually preserved, in contradistinction to RCC. There may be obliteration of the renal sinus fat by tumor [88–98].

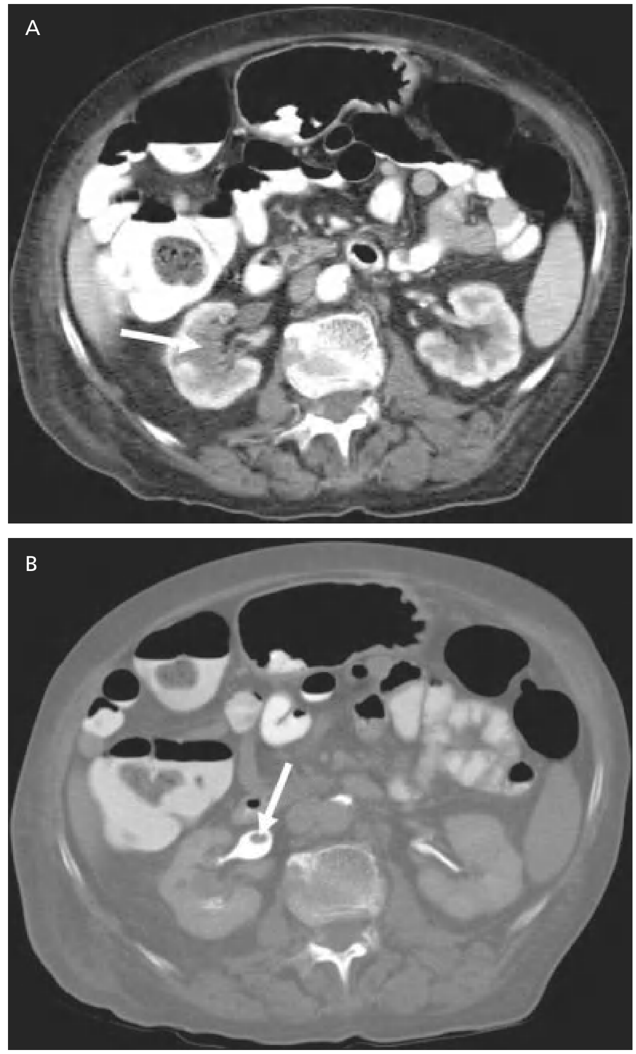

Figure 109.23 Transitional cell carcinoma. (A) CT scan obtained during the corticomedullary phase shows a hypodense mass (arrow) in the right renal pelvis and central pyramids. (B) CT scan obtained during the excretory phase shows a central mass and nodular tumor (arrow) within the right renal pelvis.

CTU is the primary noninvasive imaging test for the diagnosis and staging of upper urinary tract TCC. As stated before, MRU is an evolving technique for evaluating these lesions. Unfortunately, large studies comparing MRU with excretory urography or with CTU are lacking. MRU suffers from significant limitations of poorer spatial resolution than CTU, its inability to depict small amounts of calcification, and various artifacts, including motion artifacts from breathing and peristalsis. Moreover, the T2* effect of concentrated gadolinium excreted in the collecting system renders significant difficulties in evaluating the renal tract in

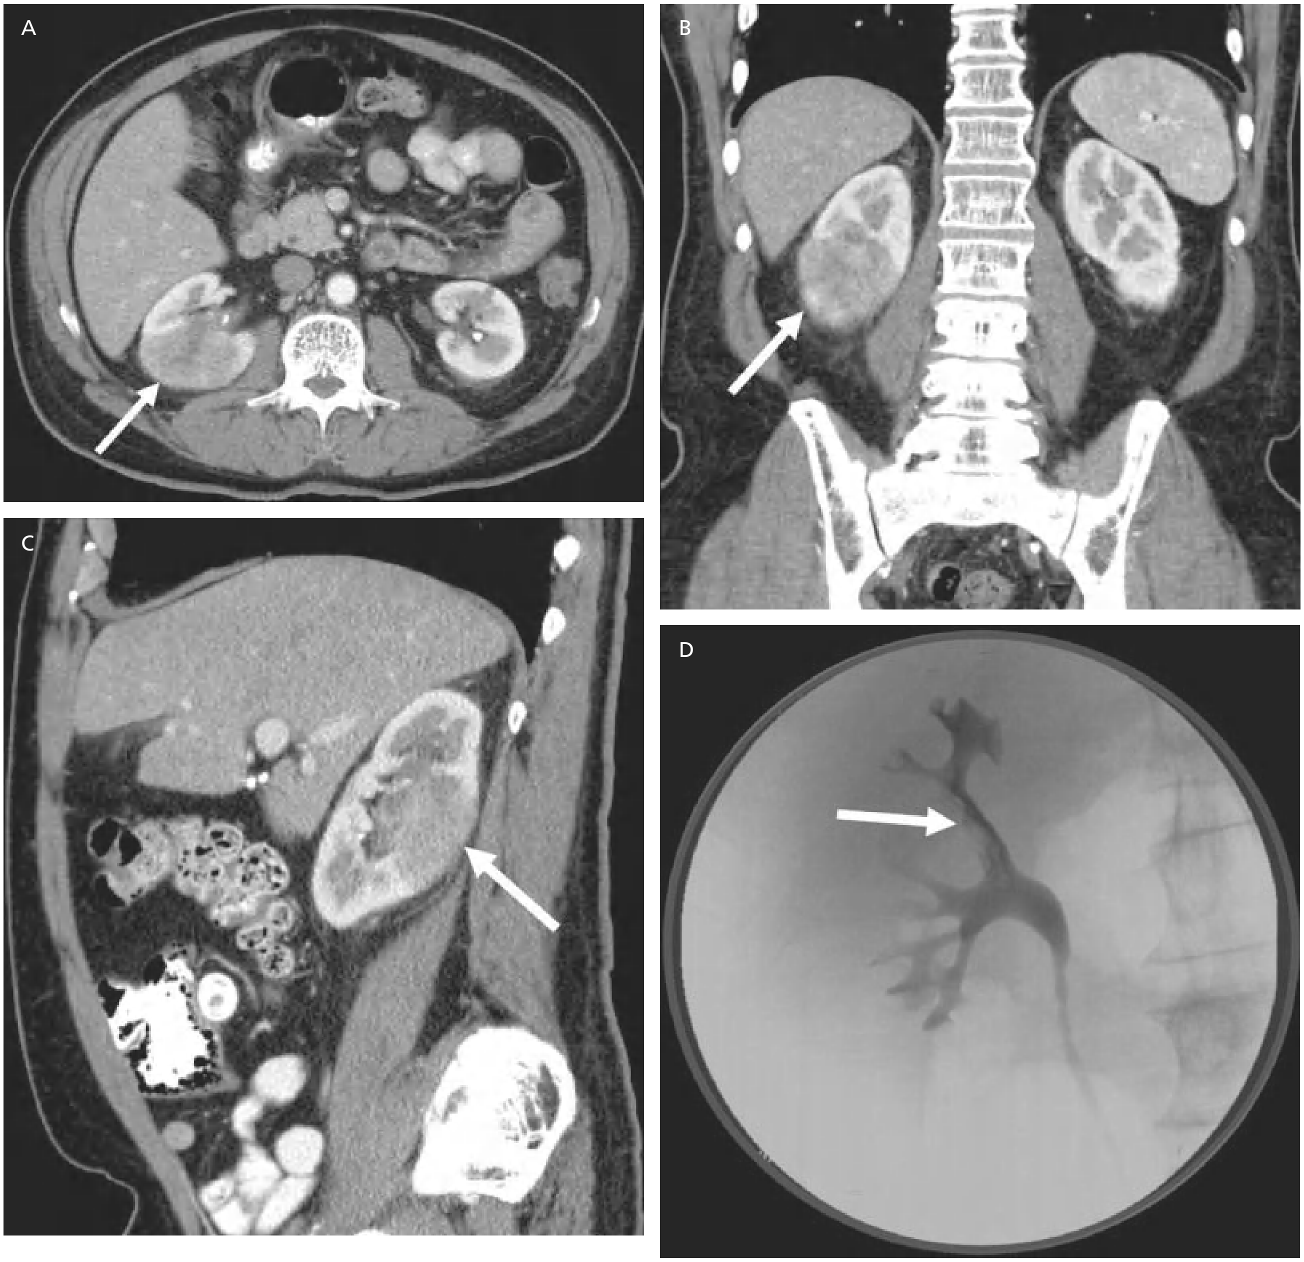

Figure 109.24 Transitional cell carcinoma of the right kidney: imaging findings. (A) Axial, (B) coronal, and (C) sagittal CT images show a large hypodense mass (arrows) extending from the renal pelvis into the renal cortex. (D) Retrograde pyelogram image shows the mass (arrow) deforming the renal pelvis.

the contrast-enhanced excretory phase T1-weighted sequences [24–27].

TCC is isointense to the renal parenchyma in both T1- and T2-weighted sequences so that MRU is best performed with gadolinium. The clinical role of MRU in patients with suspected TCC currently is limited, and should be considered as a first-line examination only when the patient has a contraindication to CTU, such as an allergy to iodine-based contrast agents [24–27].

Renal lymphoma

The kidney is one of the most common sites of extrarenal lymphoma. Nearly one-third of patients with non-Hodgkin lymphoma will have renal involvement at autopsy. Indeed, lymphoma is the third most common metastasis to the kidney following carcinoma of the lung and breast. The antemortem diagnosis is only made in 0.5–8.3%. The cells in lymphoma infiltrate

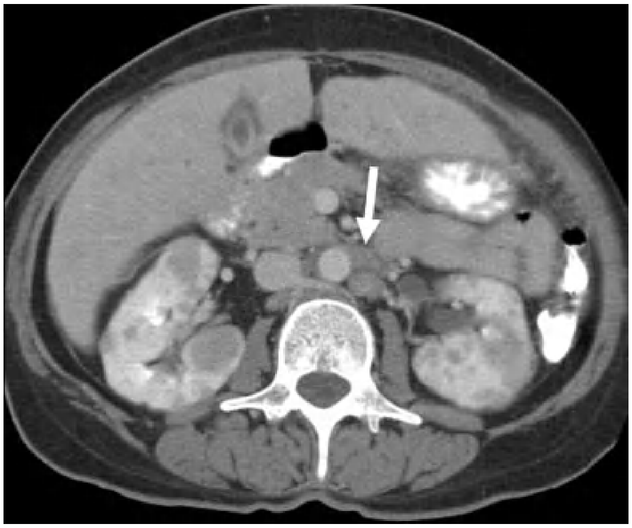

Figure 109.25 Renal lymphoma: CT findings. Multiple hypodense renal masses are present on this contrast-enhanced CT scan. Note the retroperitoneal adenopathy (arrow) as well.

between and do not destroy normal renal cells, and do not exhibit fibrosis, so the effect on renal function is typically minimal [99–102].

Since the kidneys normally do not contain lymphoid tissue, most cases of renal lymphoma are due to direct extension or hematogenous metastases. Retroperitoneal lymphoma can invade the renal capsule directly or infiltrate the renal sinus fat encasing the ureter, renal pelvis, and renal vessels. Lymphoma can then extend into the renal parenchyma via the medullary pyramids. When lymphoma involves the renal parenchyma by direct extension or hematogenous spread, it initially involves the renal interstitium, using vessels, collecting ducts, and nephrons as scaffolding [99–102].

There are five major patterns of presentation of renal lymphoma radiologically:

- Multiple renal masses that are often hyperdense compared to normal renal tissue on noncontrast CT scans due to the hypercellularity of the tumor. On contrast-enhanced scans, these lesion present as multiple, bilateral, hypodense (Figure 109.25) intraparenchymal masses, leading to a differential diagnosis of metastases, renal infarction, and renal infection.
- Diffuse renal infiltration causes nephromegaly but the renal arteries and veins remain patent despite encasement by tumor. On the early postcontrast images, the renal parenchyma remains relatively hypodense. On the nephrographic phase, relatively diminished enhancement is identified and there may be slight delay in excretion during the excretory phase. The differential diagnosis of this presentation of renal lymphoma includes RCC, TCC, and diffuse renal infection.

Figure 109.26 Perirenal lymphoma: imaging findings. Axial (A) CT and (B) MR images show a homogenous soft tissue mass (arrow) encasing the lateral aspect of the left kidney.

- The renal capsule or renal sinus may also be directly invaded by contiguous involvement from retroperitoneal lymphoma. Retroperionteal adenopathy is present and this may cause hydronephrosis.
- More rarely, renal lymphoma presents as a solitary, hypoattenuating, intra-parenchymal mass simulating a cortical tumor.
- Capsular (Figure 109.26) or perirenal involvement by lymphoma may occur with diffuse retroperitoneal adenopathy. The differential diagnosis of these cases includes perirenal hematoma and metastases [99–102].

Renal metastases

Renal metastases are quite common in patients with extrarenal neoplasms, and have been found in 7–13% of large autopsy series [17, 20]. The primary neoplasms that most commonly metastasize to the kidneys are lung (Figure 109.27), breast, and gastrointestinal cancers [85].

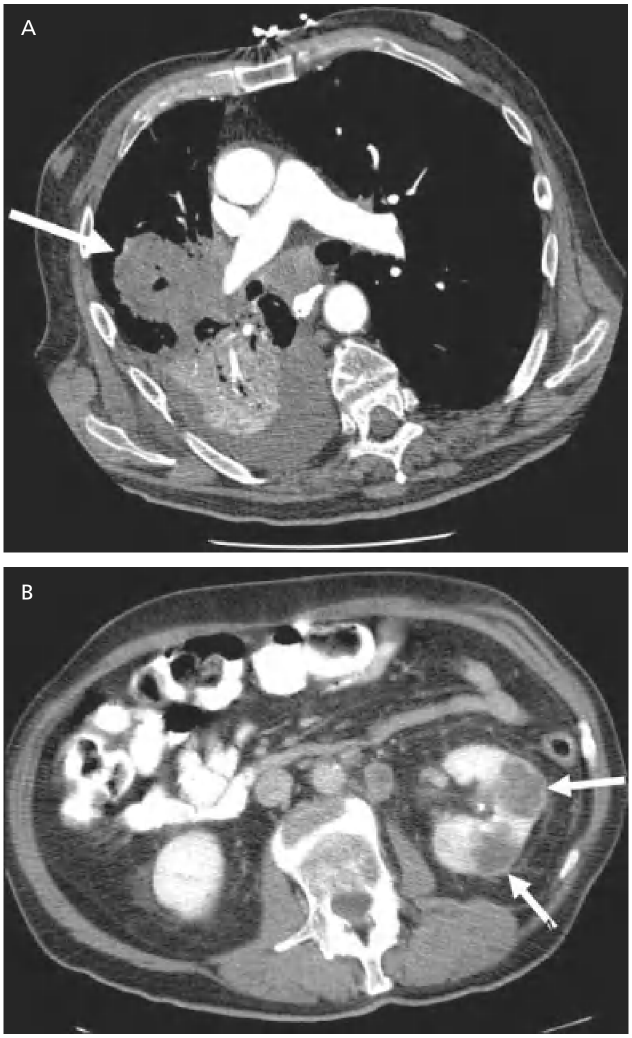

Figure 109.27 Metastatic lung cancer to the kidneys. (A) Contrast-enhanced CT scan of the chest shows a large cancer of the right upper lobe (arrow) invading the right hilum with mediastinal adenopathy. (B) Scan at the level of the kidneys show two hypodense metastases (arrows).

Figure 109.28 Nephron-sparing surgery: CT features. (A) Small hypervascular cortical right renal cell carcinoma (arrow) prior to surgery. (B) Deformity of the lateral aspect of the right kidney (arrow) is evident postoperatively.

These metastases usually have an indolent clinical behavior so were seldom discovered antemortem prior to the advent of cross-sectional imaging. By the time renal metastases are present, the patient usually has advanced disease. On rare occasions, a solitary renal metastasis may arise many years after the diagnosis of the primary neoplasm [1, 2].

Renal metastases, like lymphoma, can display an expansile or less commonly an infiltrative growth pattern. Most commonly, multiple bilateral masses are present. Solitary exophytic metastases are more common in patients with colon cancer, and perinephric tumor extension is identified in patients with melanoma [1, 2].

Patients who present with a solitary renal lesion and a known extrarenal primary tumor are a diagnostic challenge since the lesion may either be a metastasis or a synchronous renal neoplasm. The imaging findings in patients with renal metastases reflect the pathologic pattern of involvement and the nature of the primary tumor. A well-marginated hypovascular mass may be indistinguishable from a papillary RCC or lymphoma. Since infiltrative growth is atypically of renal cortical tumors, a solitary infiltrative renal mass in a patient with an extrarenal neoplasm most likely represents metastasis. Percutaneous biopsy will be needed for confirmation in these patients [26].

Imaging and nephron-sparing surgery

The increasing popularity of nephron-sparing surgery (Figure 109.28) has created a need to provide a more

consistent, reproducible scoring system that quantifies renal tumor size, location and depth, the relationship of the tumor to the pelvicalyceal system, and detailed anatomic information concerning the renal arteries and veins to assist surgical decision-making and provide effective comparisons of treatment protocols and prognosis. Kuitov and Uzzo have developed a standardized nephrotomy scoring system based on quantification of the anatomic characteristics of renal masses displayed on MDCT and MRI, to replace the rather random and descriptive way of reporting renal masses [103]. This system is called the RENAL Nephrotomy Score and consists of (R)adius (tumor size as maximal diameter), (E) xophytic/endophytic properties of the tumor, (N) earness of tumor deepest portion to the collecting system or sinus, (A)nterior (a)/posterior (p) descriptor, and (L) ocation relative to the polar line. The suffix h (hilar) is assigned to tumors that abut the main renal artery or vein. Validation of this system is currently underway at a number of institutions [103].

Radiofrequency ablation (Figure 109.29) and cryoablation are now commonly used alternatives in the management of renal tumors. Tumors less than 4 cm in size are the best candidates for ablation. Renal tumors can be classified into three areas from an interventional standpoint: exophytic, parenchymal, or central. Exophytic lesions are the safest to treat. Central tumors are more challenging because of the proximity of the renal vessels, collecting system, and ureter. Tumor proximity to the vessels may lead to direct vascular injury or inadequate tumor margin treatment due to the heat sink effect. The ureter can also be injured, resulting in laceration or stricture [10–14]. Intraoperative ultrasound can show small tumors not detected at the time of surgery by conventional means.

Recurrent cancer

Some 20–30% of patients with RCC that appears localized at the time of surgery relapse following radical nephrectomy. In the majority of cases, recurrence manifests as distant metastases rather than local disease, which occurs in less than 5% of cases. The stage of tumor at the time of presentation is the most important determinant of recurrent tumors. Other factors that increase the likelihood of recurrence include the presence of lymph node infiltration, high Furhman grade on histology, and the presence of sarcomatoid (spindle cell) architecture [104, 105].

The median time from nephrectomy to relapse is 15–18 months and 85% occur within 3 years. Tumors that involve lymph nodes tend to recur early, whereas very late relapse can be seen with isolated metastasis to the lung, bone, pancreas, or skeletal muscle. Lung metastases account for 50–60% of distant relapses. These metastases may produce parenchymal consolidation or manifest as a hemorrhagic or lymph node-related mass [103, 104].

Recurrent metastases in the pancreas typically appear hypervascular on CT (Figure 109.30) and MRI, unlike the typically hypovascular masses seen in primary pancreatic adenocarcinoma. These metastases often develop quite late following resection of the primary neoplasm [104, 105].

Figure 109.29 Radiofrequency ablation probe (arrow) deployed in a renal neoplasm. Note the patient is in the prone oblique position.

Figure 109.30 Hypervascular metastasis from renal cell carcinoma to the pancreatic head. Contrast-enhanced CT shows a large, nonobstructing mass in the pancreatic head which developed 7 years following resection of a right-sided renal cell carcinoma.

Local recurrence is unusual and produces an enhancing mass at the site of nephrectomy. These tumors may infiltrate the adjacent quadratus lumborum and psoas muscles. The colon and small bowel can be directly invaded and, when advanced, can produce mesenteric nodal disease or peritoneal carinomatosis [104, 105].

MDCT is the imaging test of choice for the detection of local recurrent disease and distant metastases. If the patient has a contrast allergy, gadolinium-enhanced MRI of the abdomen and pelvis can be performed along with a noncontrast CT scan of the chest. Although not recommended in the initial evaluation of patients with renal malignancies, FDG-PET may have a role in the detection of recurrent distal metastases, especially if conventional studies are equivocal and in differentiating recurrent tumor from postoperative fibrosis.

Conclusions

State-of-the-art MDCT, ultrasound, and MRI are leading to the earlier detection, better characterization, and improved staging of renal masses. As our increasing understanding of the diversity of renal neoplasia has been accompanied by innovative surgical and ablative techniques, cross-sectional imaging remains the linchpin in individualizing the treatment and follow-up of patients with renal masses.

CHAPTER 110

Renal Mass Biopsy

Kurdo Barwari, M. Pilar Laguna & Jean de la Rosette
Department of Urology, AMC University Hospital, Amsterdam, The Netherlands

Introduction

Unlike for other solid tumors, biopsy has not played an important role in the diagnosis of renal tumors and it was not included in diagnostic algorithms [1, 2]. Classically, a biopsy was indicated in those cases where there was a reasonable clinical doubt as to the origin of the tumor (primary renal or metastases of other cancers) or when the differential diagnosis was between a renal cell carcinoma and other causes of a renal mass (e.g. lymphoma or infection). However, in the most recent version of the American Urological Association (AUA) guidelines, biopsies are also recommended in patients with a wide range of treatment options varying from observation to surgery [1]. Another indication for a renal mass biopsy is the presence of metastatic disease, where there is a role for targeted therapy such as immunotherapy or angiogenesis inhibitors. Studies have shown that the determination of renal cell carcinoma (RCC) subtype is of vital importance since there are different treatment strategies for clear-cell RCC and nonclear-cell RCC [3].

Surveys among urologists show that the majority do not perform a renal mass biopsy even in cases of indeterminate lesions [4, 5]. The main reasons given for this were the presence of false negative results and that biopsy in most cases will not change management. A major concern was the low predictive negative value of the biopsy. The post-test probability of a diagnosis of RCC in cases with a negative renal mass biopsy has been estimated at 18% [6]. A recent comprehensive review shows that in approximately three-quarters of cases with nondiagnostic biopsies, malignancy is diagnosed at re-biopsy or surgery [7].

Currently, due to the profuse use of abdominal imaging, up to 70% of kidney tumors are accidentally discovered before symptoms arise [8, 9]. The mean size of tumors that are operated on has steadily decreased in the last two decades [10–12] and the absolute number of small renal masses (≤4 cm) diagnosed has increased, although their relative impact on the total number of tumors is still unknown. Additionally, pathologic assessment of small renal masses has evolved and the classical cut-off of 3 cm to distinguish a renal carcinoma from a benign adenoma is no longer valid. While 20 years ago every renal mass smaller than 3 cm was considered as benign, with increasing knowledge, identification of the different types of RCC and broad application of immunohistochemistry (IHC) techniques, it is known that a high percentage of these small renal masses are carcinomas [13].

The real problem does not arise in the differential diagnosis of large renal masses, where cross-sectional imaging has been proven to have a high accuracy, but in the proper assessment and differentiation of the small renal masses [13, 14]. Doubts remain about the aggressiveness of small renal masses. In an autopsy study between 1984 and 1995 it was demonstrated that 47% of all renal tumors was not clinically known. The stages of the nonclinically diagnosed tumors were mainly of T1 and T2 [9]. Another autopsy study showed a decrease in the size of nonclinically discovered renal tumors found at autopsy from 4.63 to 1.65 cm between 1955–1960 and 1991–2001, respectively [15].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Surgical contemporary series show a benign tumor incidence of 20–30% among small renal masses and this incidence is inversely proportional to size [13, 14, 16]. A definitive cut-off for aggressiveness can be established at the 3 cm diameter. While bias cannot be ruled out in the surgical series, mainly from the inclusion of cysts with different Bosniak grades, the percentage of benign masses in this size range is too high to justify an intervention without histologic confirmation of malignancy or a reasonable doubt that the mass is benign. However, interventional policies based on surgical excellence might not be ideal for the evaluation of the potential use of a test in the wider medical community.

Furthermore, partial nephrectomy, which should be considered the gold standard for small renal masses, is unfortunately underused [17], leading to overtreatment of small benign masses [18]. At the other extreme of the management spectrum, ablation or surveillance, small renal masses deserve to be biopsied for diagnosis and follow-up purposes.

Biopsy nomenclature

Before reviewing the results of renal mass biopsy, it is necessary to critically assess the nomenclature. The accuracy of a diagnostic test is measured by its sensitivity and specificity. Strictly speaking, only those studies with histologic confirmation on a surgical specimen can give accurate figures for these.

Basically, when a renal tumor is evaluated, a biopsy can deliver one of two results: diagnostic (benign or malignant) or nondiagnostic (Figure 110.1). When the biopsy is diagnostic, other characteristics such as histopathologic type and grade can also be assessed.

There are different reasons for a nondiagnostic biopsy (Table 110.1). Conceptually a failed biopsy means that there is no tumor tissue available for assessment in the biopsy specimen, although other types of tissue might be present in the sample. The reason for a failed biopsy could be a technical failure of the puncture method (e.g. misfire or malfunctioning of the biopsy gun) or an incorrect sampling. Incorrect sampling is sometimes unavoidable due to the nature of the renal tumors: these may contain necrotic and fibrotic tissue, or be mixed in nature with solid and cystic components. Also, the presence of normal renal tissue implicates that the sampling is incorrect as very few renal masses are composed of normal renal tissue. The presence of fibrotic, inflammatory, fatty or necrotic tissue in the specimen will mean that a diagnosis cannot be made from it.

In indeterminate (or inconclusive) biopsies, tumor tissue is present in the biopsy specimen but it is impos-

Table 110.1 Nomenclature of the nondiagnostic biopsies based on the sample findings, and reasons leading to a nondiagnostic result.

Nomenclature	Tissue in the sample	Reasons
Failed biopsy	Absence of tumor cells (other types of tissue may be present)	Technical failure (e.g. misfiring) Erroneous sampling (e.g. normal kidney, fibrosis, fat, inflammation, necrosis, blood)
Indeterminate (inconclusive) biopsy	Impossibility to differentiate benign from malignant cells	Insufficient cells Morphologic overlap Cellular heterogeneity

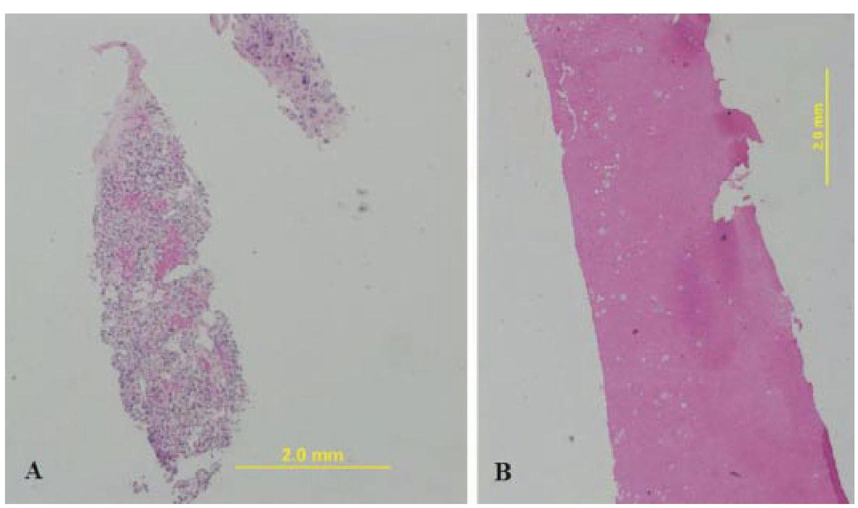

Figure 110.1 (A) Diagnostic and (B) nondiagnostic (fibrin) core biopsy of a renal tumor.

sible to determine the biology of the cells. In this case, IHC techniques may be of help if enough tissue is available.

Definitions in the literature are confusing and a certain overlap between failed, incorrect sampling and indeterminate biopsies is unavoidable. Diagnostic yield is the rate at which biopsies establish a diagnosis. Diagnostic biopsies can also give false results, both positive and negative, and the sum of these is the rate of inaccurate biopsies. Accuracy is then calculated from the total number of diagnostic biopsies.

Besides the technical failures and the indeterminate biopsies, benign nontumoral conditions (e.g. normal renal parenchyma) found in the biopsy specimen will be classed as diagnostic by some and nondiagnostic by others. Variations in results are conditioned by the lack of standardization of the taxonomy but also by the well-proven interobserver variability among pathologist. Interobserver variability may be responsible for an up to 11% differences in the rate of nondiagnostic biopsy, both for core biopsy (CB) and fine needle aspiration (FNA) [6, 19–21].

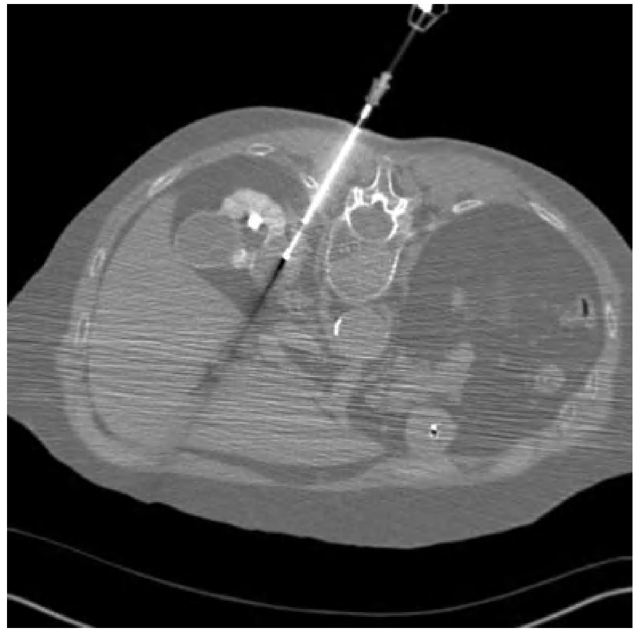

Figure 110.2 CT-guided biopsy of a renal mass in the right kidney (patient in the prone position).

Renal biopsy technique

There are two aspects when considering the technique of percutaneous renal biopsy: the type of image guidance and the type of biopsy performed [CB or cytologic aspiration (FNA)].

Image guidance

Most renal biopsies are performed percutaneously and are supported by image guidance using computed tomography (CT) or ultrasound. The biopsies are normally performed under local anesthesia in an outpatient setting. When performing biopsies during surgery or *ex vivo*, direct vision can be used. Compared with *ex vivo* renal mass biopsies, recent studies with imaging-guided percutaneous renal mass biopsies have shown better outcomes in terms of failed or indeterminate biopsies [22]. The outcomes of biopsies performed using ultrasound, CT or magnetic resonance imaging (MRI) are similar and therefore the choice between the radiologic modalities should be made on other grounds [23–26]. MRI-guided biopsy is not widespread as it entails the use of the more costly nonferromagnetic needles [23].

Ultrasound

Ultrasound guidance appears to have several advantages: it is generally available and less costly, results in less radiation, most urologists can perform it themselves, provides realtime and multiplanar imaging, and the device is portable. However, not all lesions can be visualized on ultrasound and anatomic structures, such as the ribs, and gas can obscure visibility. Finally, performing ultrasound-guided renal biopsies requires a significant learning curve. Visualization of the needle tip on ultrasound can be improved by several methods [27]. Biopsies can be performed using a guide or "freehand."

Computed tomography (Figure 110.2)

Advantages of CT guidance are that most renal tumors can be identified after contrast injection and that the puncture of intratumoral changes can be avoided to optimize the results of the biopsy (e.g. hemorrhagic zones that can result in necrosis). Adjacent organs can be optimally identified and the technique is easier to master. These advantages are even more significant in obese patients. However, realtime CT imaging is potentially hazardous for the investigator and patient due to radiation exposure. It is possible due to manipulation of the needle that the biopsy is performed outside the selected target, resulting in false-negative of nondiagnostic biopsies.

Type of biopsy

Fine needle aspiration

FNA or cytologic aspiration is performed under image guidance. When the patient is properly positioned, the

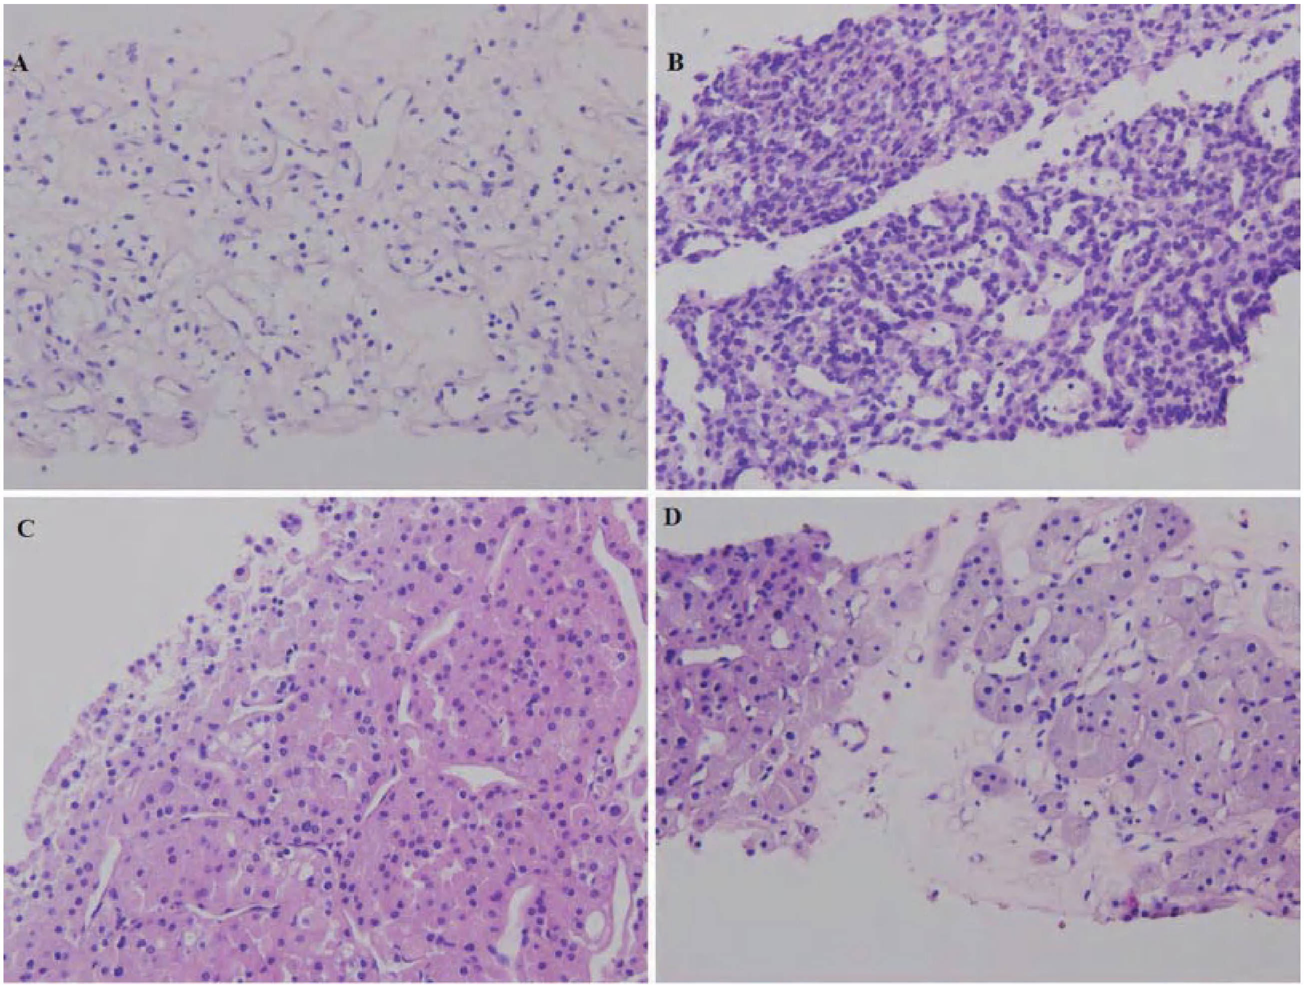

Figure 110.3 Histopathologic core biopsy samples (H&E staining) of different subtypes of renal cell carcinoma and oncocytoma: (A) clear cell RCC; (B) papillary RCC; (C) chromophobe RCC; (D) oncocytoma.

most suitable needle path is chosen. A guiding cannula is advanced onto the tumor surface and the needle is passed through the cannula into the tumor, trying to avoid possible necrotic areas. The cannula is used to avoid direct contact between the tumor and surrounding retroperitoneal tissue, decreasing the risk of tract seeding [27, 28]. The needle is then moved back and forth within the tumor to collect the cells. Traditionally, negative pressure with a syringe is applied on the needle in order to collect more cells. Another method that does not use negative pressure is Zajelda's fine needle capillary technique. This tends to reduce the amount of blood in the sample, but may result in fewer cellular smears [23]. If a CB and FNA are to be performed in the same session, the FNA should be performed first, to reduce the amount of blood in the cytologic specimen [23]. The aspirate is placed on slides and smeared directly. An on-site cytotechnologist can immediately determine the quality of the specimen, which should increase the rate of diagnostic FNAs and subsequent CBs since correct needle placement is ensured [23].

Cytologic examination can provide cytologic detail that is sometimes superior to that seen in CBs (Figure 110.3). FNA samples can be used to prepare cell blocks which are helpful to identify specific histoarchitectural features and to perform IHC studies. A recent study has shown excellent results with an improved agar microscopy which comprises processing the aspirate of FNA by centrifuging it in agar. This technique results in concentrated cell blocks composed of fragments and loose cells that are suitable for slicing and subsequent histologic interpretation with IHC [29]. Additional testing, such as flow cytometry, fluorescent *in situ* hybridization (FISH), apoptosis assays, and picrosius red F3BA staining, are also possible with FNA [23].

Core biopsy

A CB is performed with a hollow needle, allowing it to remove small but solid samples of tissue suitable for fixation and histologic examination (Figure 110.4). The needle has a cutting edge that allows tissue samples

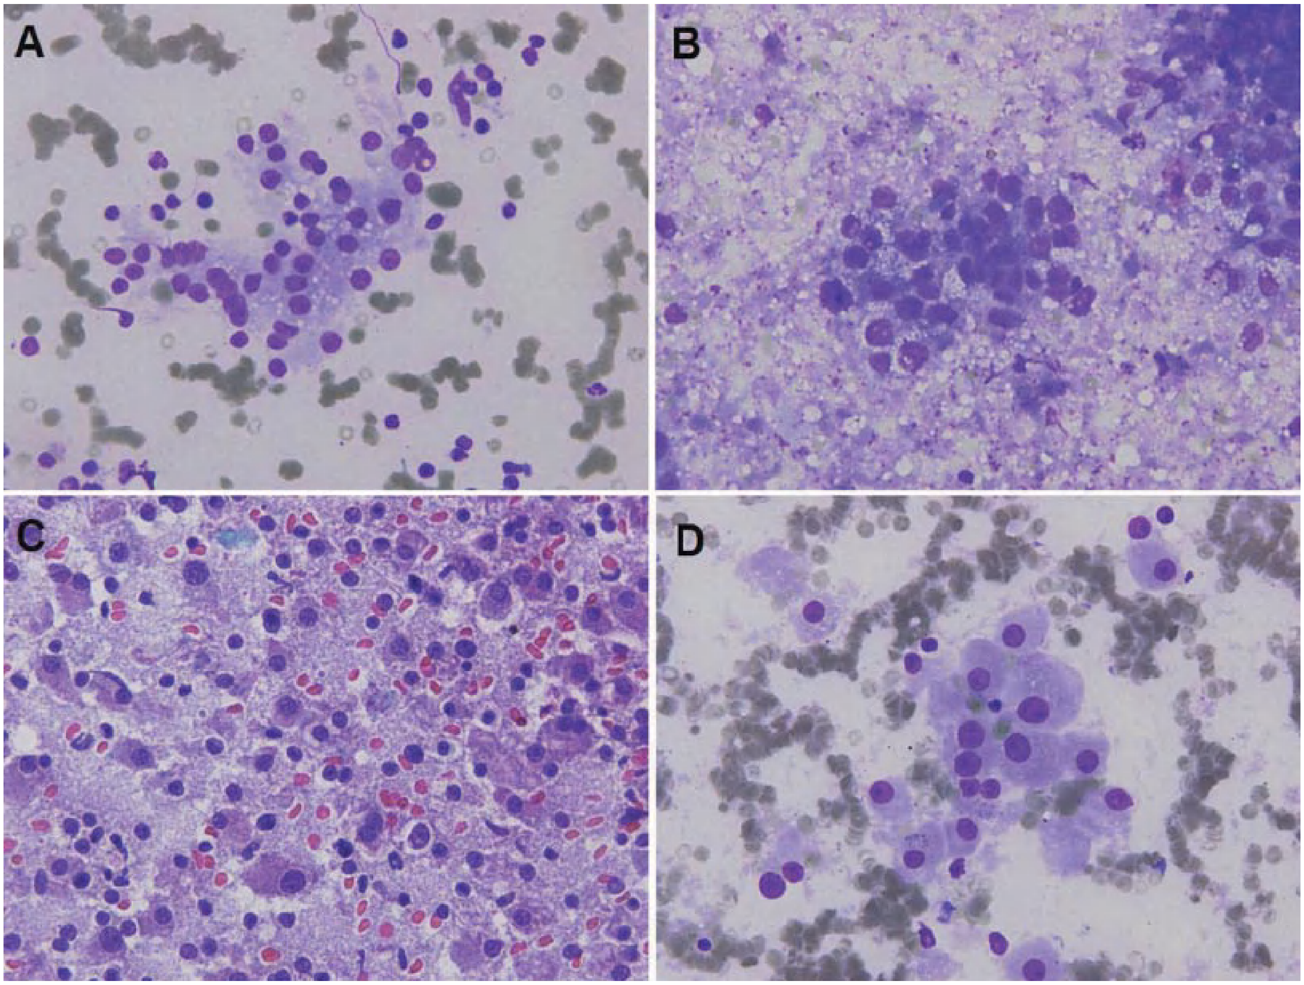

Figure 110.4 Fine needle aspiration biopsy samples (Giemsa staining) of different subtypes of RCC and oncocytoma: (A) clear cell RCC; (B) papillary RCC; (C) chromophobe RCC; (D) oncocytoma.

larger than 1 cm in length to be removed. Thicker needles than for FNAs are used (17G or 18G). The risk of complications does not increase with the use of these needles [25, 30–39]. Usually, 18G or 17G needles are used with an automatic biopsy gun to obtain tissue samples of 15–22 mm in length. The quality of the core should be checked at the time of the biopsy, in order to repeat it if there are doubts about its quality.

Technical considerations

There are technical considerations with both FNA and CB to improve the quality of the sampling and to maximize the results.

The choice of radiologic imaging depends on tumor location, size, access feasibility, visibility and individual preference. Imaging is used to avoid areas suggestive of pathologic necrosis or cystic areas. The same considerations apply to the choice of biopsy type, FNA or CB. In general higher accuracy has been shown for CB, although experienced groups achieve the same results with FNA [40]. The ideal is to perform both types of biopsy during the same procedure.

Larger needles have shown better results in terms of sample quality, and there is no increased risk for complications when comparing 18G to 22G needles [23, 25, 29, 36–39) (Figure 110.5). Most recently, Breda *et al*. compared the *ex vivo* performance of three distinct needles (14G, 18G, and 20G) in a blinded study [41]. One core biopsy was obtained with each needle from 31 tumors. Biopsies were analyzed by H&E and a standard IHC panel. All the biopsies performed with the 14G and 18G needles provided sufficient tissue for diagnosis, whereas the technical failure rate for the 20G needle was 14%. Sensitivity to distinguish between benign and malignant tumor was high for the three needle calibers, but specificity was lower for the 20G needle. Histologic accuracy was 92%, 97% and 81% for 14G, 18G, and 20G needles, respectively. Grade accuracy was consistently low for the three needles and in the range 40–56%. These

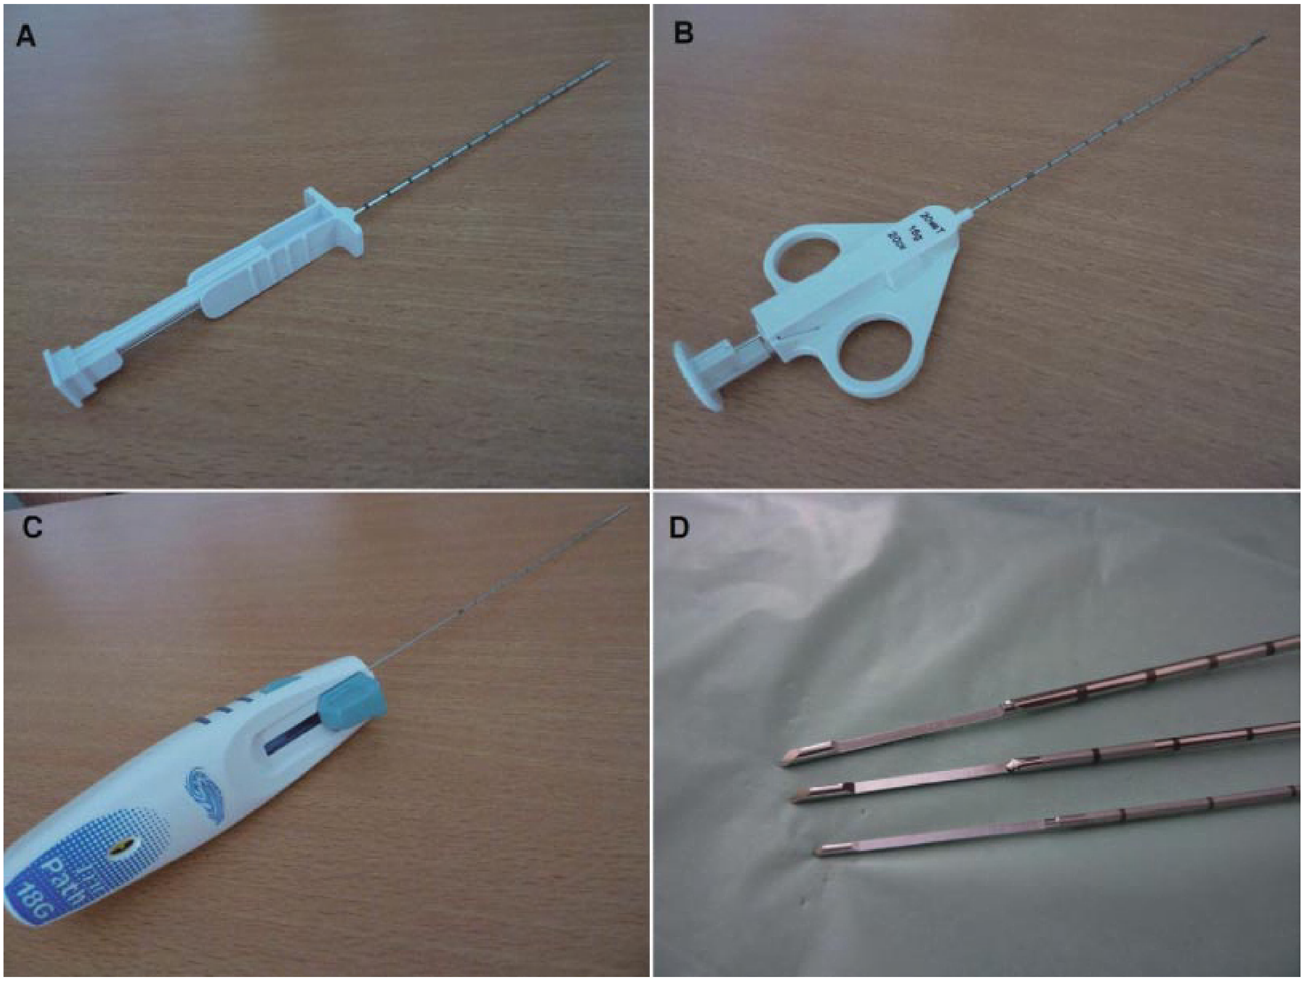

Figure 110.5 Core biopsy needles: (A) manual 14G needle; (B) semi-automatic 16G needle; (C) fully automatic 18G needle. (D) Needle tips of the 14G, 16G, and 18G biopsy needles (top to bottom). All cores obtained are between 18 and 20 mm in length.

authors concluded that at least one core biopsy with an 18G needle offers the highest accuracy in histologic diagnosis [41]. The change to thicker needles could be at least partly responsible for the increasing accuracy and decreasing failure rate of the biopsies [22].

Different type of needles are available to perform a CB. Automatic Tru-Cut needles are easier to manage than the original manual Tru-Cut needles.

There are no studies in the literature comparing the results for different number of samples. However, the number of CBs advised in the literature is at least two [22, 23, 33]. For FNA, as many passes as necessary should be performed to ensure a diagnostic smear. As mentioned above, ideally the cytologist should prepare the smear directly after puncturing ("on site") and examine it immediately to ensure the presence of cells and to give the opportunity to repeat the cytologic aspiration if necessary.

In both CB and FNA it is recommended to use a cannula that is wider than the biopsy needle to be used. This cannula is advanced under imaging onto the surface of the tumor and remains stable during the whole procedure. The biopsy needle is advanced through the cannula, which allows a number of passes or biopsies to be performed without the risk of contamination or seeding, and avoids manipulation of the chosen tract.

Tumor size does affect the results of the biopsy. Since larger tumors more frequently have central necrosis, it is recommended to perform a peripheral and a central biopsy in tumors smaller than 4 cm and two peripheral biopsies for tumors larger than 4 cm [42].

Although bleeding complications are rare (see below), coagulation abnormalities should be corrected prior to biopsy, anticoagulants should be stopped when possible, and some hours of rest are recommended after biopsy.

CBs are best preserved in formalin until fixation and analysis.

Complications

Potential complications of percutaneous renal biopsies are bleeding, tumor seeding along the needle tract, arteriovenous fistula, infection, and pneumothorax.

There is enough evidence to affirm that minor complications are infrequent, occurring in less than 5% of all biopsies performed for renal masses. Catastrophic complications are extremely rare and mortality has not been described in the recent literature [22]. The most frequent complication is hemorrhage [22, 43, 44]. There are controversial reports on the correlation between needle size and rate of complications [39, 45, 46]. The correlation is highest when 15G needles are compared with 21G needles; however, as mentioned above there is no significant difference in complication rate when 18G and 21G needles are compared [46].

The most feared complication of renal biopsies is tumor seeding. However, in all recent series (from 1994 onwards) of renal tumor biopsy, no cases of tract seeding have been reported. This might be explained by the widespread use of a guiding cannula for renal biopsy [23, 47]. Urothelial carcinomas have a higher tendency to seed along the tract than RCCs. Therefore, when urothelial cell carcinoma is suspected, a percutaneous biopsy for diagnostic purposes is not recommended [47, 48].

Other complications occur very rarely. An arteriovenous fistula should be considered in cases of persistent bleeding [49]. When the renal biopsy is performed by a posterior approach, pneumothorax has been reported in 14–29% of cases, although clinically significant pneumothorax is uncommon (<1%) [44, 48]. To further minimize the risk of a pneumothorax, the puncture should be performed in expiration and the needle should be positioned subcostally. Some upper pole tumors can be punctured using the paravertebral approach, which involves the injection of saline in the paravertebral space to displace the pleura laterally [50].

There is no evidence that a renal mass biopsy can complicate a subsequent partial or radical nephrectomy [39, 51, 52].

Results

From the 1970s onwards, many studies have been performed on the diagnostic accuracy of renal mass biopsy. Early studies focused on cytologic aspiration with Chiba needles, but the incorporation of automatic fine CB needles minimized trauma and allowed core samples to be obtained that were easier to analyze.

In 2008 Lane *et al*. published an extensive review on the subject [22]. They divided the studies chronologically between those conducted before and from 2001 onwards. Before 2001, 27 studies were considered, in two of which "*ex vivo*" tumor biopsy was performed. After 2001, seven clinical studies and three *ex vivo* studies were considered. An overall diagnostic accuracy of 88.9% was reported for the earlier period (including *ex vivo* biopsies) and a 96% clinical accuracy (excluding *ex vivo* biopsies) for the later period. Although no statistical comparison was available, these figures suggest an improving trend in the diagnostic performance of the biopsy. Whether a 7% difference in accuracy is of clinical significance remains unknown, but it is worthwhile. Furthermore, false-negative and -positive rates both decreased between periods.

Accuracy of the biopsy was calculated based on the number of successful biopsies. Biopsy failures defined as "the inability to obtain an amount of tissue sufficient for diagnosis" were excluded from the accuracy assessment. Consequently, in clinical practice, the physician has to be aware that diagnostic yield is different from accuracy, as the biopsy failures accounted still for 9% and 5.2% for the periods before 2001 and from 2001 onwards, respectively. Indeterminate biopsies were included in the accuracy assessment in the review. However, an indeterminate biopsy is in fact a nondiagnostic biopsy. The sum of technical failures plus indeterminate biopsies ("no definitive diagnosis possible using the available techniques") was 19% and 10% in the respective periods. In summary, biopsy has a high accuracy in the modern era, but nondiagnostic biopsies still account for an overall 10% in general series irrespective of the tumor size.

When considering these results, some limitations of the review, most of which were pointed out by the authors, must be mentioned. First, the studies included in this review compared the biopsy results to numerous different gold standards. These index tests varied from pathologic examination of the specimen after surgical excision to radiologic follow-up of nonextirpated tumors [7]. For example, in the period before 2001, surgery and consequently surgical specimen available for comparison was noted in only 49.5% of the cases previously biopsied, excluding the *ex vivo* biopsy studies for which a surgical specimen was obviously available in all cases. The number of cases with surgical specimen available for comparison increased to 54% in the second study period. Together with the recent knowledge that the lack of radiologic growth does not necessarily mean absence of malignancy [53], this means that the results of the biopsies were compared to a strict index test in only half of the cases.

Second, the percentage of pathologically confirmed renal carcinomas was 70.5% before 2001 and 82% from 2001 onwards, which could suggest that selection criteria based on imaging could have improved over time.

Third, heterogeneity among series in both periods in terms of selection criteria, technical issues (e.g. needle used, histopathologic type of biopsy), and the different number of cases included precludes sound statistical comparison.

All the above mentioned reasons may be sources of bias in the interpretation of the analysis, and overestimation

of the biopsy accuracy cannot be ruled out, but neither can the improving trend be denied.

In an attempt to clarify the results, we further examined those series where pathologic confirmation was obtained in the form of a surgical specimen in 100% of cases, whether *ex vivo* or in the clinical setting, including with a preoperative percutaneous biopsy. Results of biopsy of small renal masses are also considered separately, as results from general series may not be extrapolatable to these masses.

Ex vivo biopsies

Several studies have evaluated the accuracy of the *ex vivo* (in bench) biopsy for the diagnosis of renal tumors [6, 20, 21, 30, 31, 41, 42, 54, 55]. The accuracy of surgical excision (nephrectomy or partial nephrectomy) biopsies taken under direct vision were compared to the definitive pathologic diagnostic of the surgical specimen in 100% of the cases. In most of the studies pathologists evaluating the biopsy were blinded to the definitive histopathologic results.

Ex vivo CBs were sufficiently accurate to be able to differentiate between a malignant and a benign renal mass (Table 110.2). Overall accuracy varied from 72% to 90%, and was not lower for FNAs [20]. The rate of nondiagnostic biopsies varied from 2% to 20% with a trend to be higher than in the modern percutaneous biopsy studies [22]. Using the same nomenclature as in the article by Lane *et al.* [22] is used, Kummerlin *et al*. described a rate of failed biopsies (called *nondiagnostic*) between 8% and 16% for the five pathologists involved in the study, and a rate of indeterminate biopsies (called *nonconclusive*) between 0% and 8% [19]. This fact may be explained by the lack of visualization of the entire tumor, as can occur during imaging or in the absence of needle stabilization during percutaneous puncture. Subtype differentiation between oncocytoma and chromophobe RCC remains problematic (see Figures 110.3 and 110.4). Kummerlin *et al*. found a good overall accuracy for *ex vivo* FNA in differentiating between malignant and benign masses [18, 20]. However, again there was a substantial interobserver variation regarding the subtype differentiation other than for clear-cell RCC.

When interpreting the results of in-bench biopsy studies, it has to be taken into account that this *ex vivo* setting is only partially comparable to clinical practice, where percutaneous biopsies will be the standard.

Percutaneous biopsy compared with 100% surgical specimens

The number of studies on the accuracy of percutaneous renal mass biopsy based on 100% comparison of the preoperative samples with the surgical specimen is very low.

Before 2001 only three such studies were identified in the review of Lane *et al.* [56–58]. In these studies accuracy for the diagnosis of RCC varied from 40% to 94%; the rate of biopsy failures varied from 0% to 22% and the rate of indeterminate biopsies from 4.3% to 36%. False positives were almost nonexistent (0–2.2%), but false negatives accounted for 0–24%. These results are clearly insufficient to justify the systematic use of percutaneous biopsy in the diagnostic setting. However, comparison with modern data is precluded as different needles, mostly 21G and 22G, were used, and in two of those studies biopsy was guided by old ultrasound devices.

After 2001, only three more reports are available in the literature in which the percutaneous renal mass biopsy has been compared in all cases with the surgical specimen [54, 59, 60] (Table 110.3).The sensitivity of percutaneous core biopsy to detect malignancy proven at surgical specimen varies from 91.4% to 93.5% and the negative predictive value from 50% to 81.3%. The rate of nondiagnostic biopsies was very low in these three modern studies, in the range of 2.4–7.1%, although in some cases a repeat biopsy was necessary to reach a diagnosis. Correct RCC subtype determination varied from 77.5% to 91% and correct Fuhrman nuclear grade from 51.5% to 76%, with the grade mainly being underestimated on CB.

Biopsy in small renal mass

The performance of renal mass biopsies in small renal masses (SRMs; ≤4 cm) is of utmost importance for a number of reasons. There is a high percentage of benign masses among the small renal tumors [13, 61], radiologic distinction between malignant and benign may be extremely difficult in this size range [14], and in spite of the low biologic potential of small RCC, some will be of high grade [16, 18]. The clinical scenario becomes even more complicated as a considerable number of those SRMs are accidentally found in older patients with comorbidity. Especially in SRMs, a preoperative histologic diagnosis may lead to a change in management.

In general, the sensitivity of renal biopsy in SRM is lower when compared with general series on renal biopsy (including all tumor sizes). The biopsy failure rate increases in SRMs. A rate of biopsy failure as high as 37% has been reported in renal masses smaller than 3 cm versus 9% in tumors larger than 3 cm [52].

Table 110.4 gives an overview of published studies on biopsies in SRM. As expected, biopsy results for SRMs are less accurate than in larger masses, with histologic confirmation by means of surgical specimen in 30–78% of cases [22]. The rate of nondiagnostic biopsies is also

Table 110.2 Results of *ex vivo* biopsies. Pathologic surgical specimen available in all cases.

higher in SRM, either because of technical failure or because of indeterminate results.

It was demonstrated that when the result of a biopsy is malignant, subtype determination is possible in 93% of the biopsies; however, IHC is necessary in a substantial number of cases. Concordance with the surgical specimen is high (91–100%) [62, 63]. Fuhrman nuclear grade was correct in 68%, with a lower concordance than for subtype (60–100%), as was the case in larger renal masses [62–64].

Accuracy for histology and grade

Kidney tumors are known to show intratumoral heterogeneity and therefore subtype identification can be misleading when biopsies are assessed. However, in the modern series an overall accuracy of 94% in identifying the correct histologic subtype was reported [22]. Similar results for grade accuracy have been reported for SRMs, although IHC was necessary in most cases [62].

One of the major problems in differentiating subtypes of RCC is the distinction between oncocytoma and chromophobe RCC, since hybrid tumors containing areas of benign oncocytoma and malignant chromophobe RCC exist [60]. This issue remains a challenge for the pathologist, especially when limited tissue is available, as is the case with biopsies. New auxiliary techniques, such as genetic profiling, polymerase chain reaction (PCR), and FISH are under development to distinguish chromophobe RCC, oncocytomas, and other subtypes of RCC with more accuracy [32, 33, 67, 68].

Heterogeneity of renal tumors is also hindering correct determination of Fuhrman's nuclear grade by biopsy. In two large recent series, Fuhrman's nuclear grade was correctly determined in 70% [51] and 83% [42] respectively. In all the discordant cases, the actual grade found in postoperative pathology was within one grade of the grade found at biopsy. A higher accuracy (76–100%) is obtained when the nuclear grade of tumors is grouped into "low grade" (Fuhrman I–II) and "'high grade" (Fuhrman III–IV) [51, 52].

Biopsy during thermal ablation

When performing thermal ablation of small renal tumors, such as cryoablation (CA) or radiofrequency ablation (RFA), information on the pathology of the ablated mass can only be gained through biopsy of the tumor, since the specimen is not extirpated. This information has not only diagnostic purposes but may impact follow-up policy. An additional use of biopsies in the frame of ablation therapy is in determining the presence of residual tumor.

Two recent meta-analysis have compared CA with RFA [69] and percutaneous ablation with surgical ablation, including laparoscopy [70]. Biopsy of the mass was performed in 82.3% of the CA, in 62.2% of the RFA, in 84% of the percutaneous procedures and in 88 % of the surgically assisted ablations [69, 70]. Overall, between 54% and 64% of the biopsies confirmed RCC, 12.7% showed benign pathology and 33.5% had unknown of undetermined pathology [69]. With the limitations derived from the lack of well designed comparative studies it becomes evident that biopsy of the tumors is widely adopted during ablation treatments but in the case of RFA where still 40% of the patients are treated without information on tumor biology.

The rate of nondiagnostic biopsy varies from 0% to 23% in those series of percutaneous ablation [71–74] and from 0% to 30% when tumor biopsy is performed during laparoscopic ablation [75–80]. These figures are similar to the nondiagnostic rates described for SRMs (see Table 110.4) as the tumors treated by ablation are in this size range. At least during laparoscopy-assisted ablation, modification of the biopsy technique, by activating the firing mechanism of the biopsy gun externally to the target tissue, led to a higher diagnostic yield in a small clinical series [77]. The criteria classifying a biopsy as nondiagnostic or benign varies between groups, which may explain the broad range of nondiagnostic or benign results. As an example, normal renal tissue, fibrotic tissue or necrotic tissue are distinctly classed as benign by some and nondiagnostic by others [78, 80]. In fact, the stricter the nondiagnostic criteria are, the higher the nondiagnostic rate of the biopsy.

Tumor biopsies can also be taken immediately after ablation to minimize risk of bleeding or tract seeding. In this situation, the pathologist can identify RCC architecture both after RFA and CA and the diagnostic yield of the preablation and immediate postablation biopsies is not statistically different [81–83].

Success after ablation therapy is mainly determined using cross-sectional imaging with contrast. Lack of contrast enhancement indicates absence of tumor recurrence [84]. However, the presence of viable tumors in the ablated area is not completely ruled out by the lack of enhancement on CT or MRI [85]. Therefore, some centers have performed an additional postablation biopsy to assess the success of the ablation. A study on the correlation of radiographic imaging and histopathology showed that in 24% of patients treated by RFA, the 6-month postablation biopsy showed viable renal cancer cells even though there were no signs of radiologic enhancement at that time [86]. The 6-months postcryoablation biopsy was consistently negative in all nonenhancing masses. Therefore, the sensitivity of nodular enhancement at 6 months after RFA to detect a positive biopsy was only 38.4%, with a specificity of 91.3%. The results for cryoablation were superior, with a sensitivity and specificity of 77.8% and 95.1%,

respectively. In contrast, a study on RFA lesion biopsy more than 1 year after ablation showed no vital lesion [87]. It is therefore advisable to use NADH or other oxidative stress stains when assessing biopsy after ablation [88].

Additional pathologic methods

RCC subtyping was originally performed using a light microscope and standard H&E staining. The diagnostic accuracy in differentiating benign from malignant renal mass is substantial, but for determining RCC subtypes the accuracy is lower, since complex and overlapping morphologic features exist. As described earlier, this results in the interobserver and intraobserver variability of subtyping [19, 20].

For a long time research to improve subtyping of renal tumors had no priority since there were no clinical consequences. However, there has been interest in subtype determination of RCC following the incorporation in clinical practice of targeted therapies. Correct determination of RCC subtype can be of capital importance since paradigms for specific RCC subtypes may not apply to other subtypes. Therefore, a more accurate differentiation of RCC subtypes is desirable.

Differences among RCC subtypes at the DNA or RNA and the protein level have been explored in order to improve the accuracy of subtype differentiation. Although different subtypes of RCC show overlapping histologic features they are biologically distinct. This is obvious when the cytogenetic abnormalities of different subtypes are observed: different subtypes have characteristic abnormalities, such as chromosome 3p aberrations in clear-cell RCC and trisomy 17 in chromophobe RCC [89]. These characteristic differences imply that the different subtypes are distinguishable by mapping this genetic expression.

One method to perform a molecular gene profiling analysis is DNA microarray. This has shown differences in gene expression profiles between subtypes of RCC and therefore it differentiates between the histologic subtypes of RCC [90–92]. By analyzing the mRNA expression ratios of different genes in different subtypes of RCC, the individual subtypes can be differentiated: high CA9 expression in clear-cell RCC, AMACR in papillary RCC, and CLCNKB in chromophobe RCC and oncocytoma [93] which facilitates a molecular diagnostic algorithm. It has been demonstrated that renal masses can be accurately classified on CBs using a combination of histopathology and molecular gene profiling analysis [30].

In order to obtain sufficient material for investigation, the genetic material harvested with percutaneous biopsy should be amplified by PCR [23, 30].

Another auxiliary technique for subtype differentiation is IHC, which localizes specific antigens or proteins in a tissue sample by binding the antigens with labeled antibodies. The formed antigen–antibody complex can be visualized by (fluorescent) staining and therefore the presence of the antigen can be demonstrated.

Several antigens have been found to be useful as a marker for subtype determination of RCC, and they are currently used in combination with histologic investigation to improve the diagnostic accuracy. It is likely that in the near future these techniques will contribute more to the diagnostic process [94–96].

Conclusions and recommendations

There is an increasing interest and trend to incorporate the percutaneous biopsy of a renal mass into the diagnostic algorithm of small renal tumors, when treatment depends on histologic subtype determination, and for ablative procedures. CB is more commonly performed than FNA. Complications are rare and mostly of low grade.

Modern series on percutaneous biopsy of renal masses show a high accuracy and a lower rate of failed or undetermined biopsies than older series. Although still scarce, those recent series with pathologic confirmation by means of surgical specimen support these encouraging results. The accuracy of histologic subtype determination in the biopsy specimen may be up to 94% and of Furman's grade up to 70%. Oncocytic features may overlap with those of chromophobe RCC.

However, when considering a percutaneous biopsy in an SRM, there needs to be an awareness that accuracy will be inferior to that reported in general series. The overall rate of nondiagnostic biopsy, either failed or inconclusive, is still high in the SRM.

Biopsies are not consistently performed during ablation therapy. When performed, the literature shows a similar rate of nondiagnostic biopsies as in the case of SRM. Biopsy immediately performed after ablation leads to the same diagnostic yield as before ablation as architectural structure is still recognizable.

Current percutaneous renal biopsy is recommended when there is a suspicion of nonprimary RCC, when an infectious cause is suspected, during ablation therapy, to decide on treatment of SRMs, for therapeutic purposes in metastatic RCC, and for documentation and follow-up purposes when a RCC is submitted to active surveillance.

CHAPTER 111
Percutaneous Radiofrequency Ablation of Kidney Tumors

Obi Ekwenna, Rajan Ramanathan & Raymond J. Leveillee
University of Miami–Miller School of Medicine, Miami, FL, USA

Introduction

The increasing incidence of renal cell carcinoma in the USA and worldwide [1, 2] is attributed to the increasing use of sectional abdominal imaging. Approximately 48–66% of all renal masses that are diagnosed, and 40% of all excised tumors are small renal masses (SRMs) [3]. SRMs are defined as tumors of less than 4 cm on abdominal imaging, of which 70–80% are malignant and 20% are benign.

Although radical nephrectomy (RN) had been the "gold standard" for treatment of organ-confined disease for several decades, growing evidence favors nephron-sparing surgery (NSS). Partial nephrectomy (PN) has now become the treatment of choice for most SRMs [4]. The evolution in incidence, presentation, and diagnosis of renal masses has prompted innovative ways of treatment with the goal of preserving renal function and decreasing morbidity.

The morbidity and mortality associated with chronic renal insufficiency with respect to cardiac events, stroke, and death are well established [5, 6]. Huang *et al*. showed that the risk of stage 3 or higher chronic kidney disease (CKD) was 20% after NSS and 65% after RN [7]. The morbidity for NSS (open and laparoscopic) includes, but is *not* limited to, urine leak, postoperative hemorrhage, wound paresthesias, hernia, flank bulge, and pain, and can be quite troublesome. The demonstration of equivalent cancer control with NSS as compared to RN has prompted the development of less invasive thermoablative techniques [like radiofrequency ablation (RFA) and cryoablation] in order to reduce the complications of NSS [8].

This chapter will focus on the development, application, and role of percutaneous RFA.

History

Biologic excitable tissue (i.e. nerve, muscle) can be stimulated readily by electrical energy with a frequency under 1000 Hz (i.e. household current of 60 A) but not by frequencies of 10 kHz or greater [9]. This basic principle was used in surgery for more than a century; from Edwin Beer (1910) and transurethral resection of bladder tumor; Henry Bugbee (1913) and an electrode to treat bladder neck obstruction; Max Stern (1926) and resectotherm for the prostate; and William Bovie and Harvey Cushing (1928) and electrosurgery [10, 11]. These inventions paved the way to the use of varying energy forms in therapeutic management of disease. The use of radiofrequency (RF) energy, an alternating electrical current (AC) with a wavelength between 10 kHz and 900 MHz, dates back to the 1960s, when RF energy was used to destroy central nervous system tissues for pain relief [12, 13]. Two decades later, Nath *et al*. and others described the use of RFA in the treatment of cardiac dysrhythmias to ameliorate aberrant conduction pathways [14–18]. The use of RFA for oncologic purposes did not occur until animal experiments were reported in the late 1980s for the treatment of metastatic liver lesions[19]. Application of thermal energy by means of radiofrequency to destroy benign or malignant tissues was

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

proved to be successful for osteoid osteomas (canine) and small primary and metastatic liver lesions (humans) [20–22].

In 1996, Zlotta *et al*. described the first application of RFA technology to renal tumors in a human models and *in vivo* [23]. In this preliminary experience involving bipolar RFA of freshly removed human kidneys in an *ex vivo* model, the kidneys were perfused *ex vivo* with normal saline at 37°C to mimic the physiologic environment. Observations made from this study revealed that large reproducible controlled lesions were present in the renal parenchyma between the ablative needles [23]. One of the oversights in utilizing this model was the effect of perfusing the entire organ with an electrolyte solution, which allowed for the creation of very large lesions that could not be reproduced *in vivo*. Later, *in vivo* human RFA of renal tumors and subsequent resection confirmed most of the findings of the *ex vivo* model, prompting multiple other investigators to further explore RFA technology in the management of renal tumors in animal models and human. Walther *et al.* described the experience with four patients who underwent RFA treatment of 14 tumors just before surgical removal of the tumors [24]. Computed tomography (CT) was obtained prior and after ablation with no toxicity reported after the procedure.

The feasibility and safety of RFA as described above paved the way for the first application of the technique with the intent to treat renal cell carcinoma [25]. In this case report of an 84-year-old man who refused open surgical excision of a solid renal mass, CT demonstrated enhancement consistent with RCC that continued to enlarge over a 3-year interval to 3.5 cm. The patient consented to percutaneous RFA. Under conscious sedation the patient underwent percutaneous renal biopsy confirming RCC. A 17G internally cooled RFA needle electrode was used under realtime ultrasound guidance into the center of the tumor. The tumor was heated to 90°C for 1 min, followed by deposition of 1200 mA of current for 12 min. The patient tolerated the procedure well; 2-h, 1- and 3-month follow-up CT showed a nonenhancing lesion. McGovern *et al.* concluded that "successful percutaneous ablation may prove to be reasonable treatment alternative in patients who are at significant operative risk or when renal preservation is desired, such as those in whom von-Hippel–Lindau disease or other conditions predispose to multiple bilateral renal tumors" [25]. This statement proved to be the beginning of an indication to use RFA as a treatment method for RCC.

Fundamental concepts of radiofrequency ablation

Heat therapies convert radiant energy to thermal energy in tissues to achieve the goal of tissue destruction. This

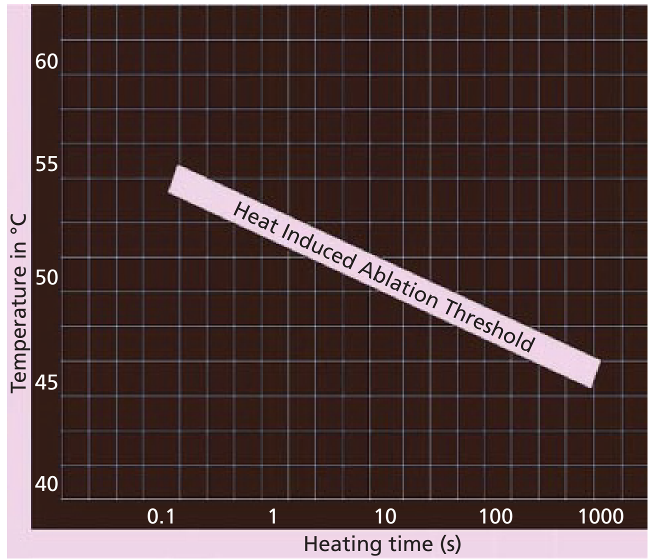

Figure 111.1 Relationship between temperature and time for thermal necrosis.

thermal energy is conducted primarily from cell to cell via diffusion in order to achieve cell death. Cell death or *ablation* is the consequence of several cellular changes, which are dependent on time and temperature (Figure 111.1).

High temperatures causes one of the following:

- Immediate cell death by disruption of cellular architecture;
- Vaporization;
- Carbonization;
- Damage to essential cellular components (i.e. DNA, RNA).

At low temperatures (e.g. 45°C) it takes hours to promote *irreversible damage to cells*; at higher temperature (e.g. 100°C) it may take milliseconds to effect irreversible damage to cells and eventual cell death [9]. High temperatures cause immediate observable changes such as gross structural damage and vaporization or carbonization. Lower temperatures may result in deactivation of cellular enzymes involved in various functions; however, the cell's structural integrity (microscopic architecture) is maintained. Within hours, it is observed that the injury will lead to cell death via oncosis, followed by cellular and organelle swelling, and blebbing. Swelling eventually results in ischemia with appropriate cellular response leading to toxic levels of calcium within the cell, causing increased intracellular acidosis, which leads to denaturing of proteins, and eventually *coagulation necrosis*.

Coagulation necrosis is characteristic of cell death via hypoxia and ablation. In general, necrotic cells show increased eosinophilia attributable in part to loss of

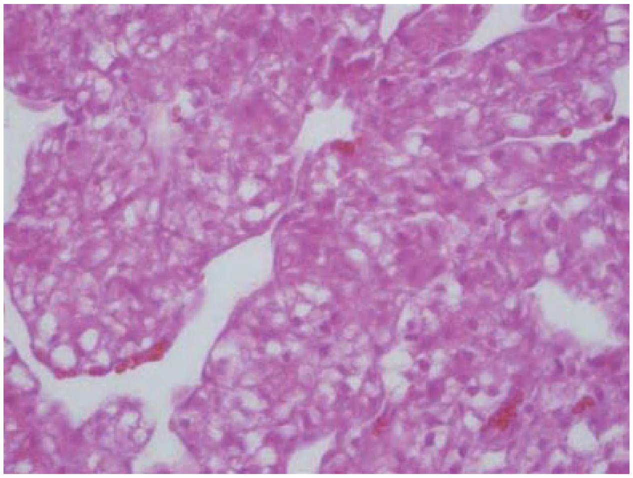

Figure 111.2 Postablation biopsy showing increased binding of eosin to denatured intracystoplasmic proteins. 60 × H&E.

the normal basophilia imparted by the RNA in the cytoplasm and in part to the increased binding of eosin to denatured intracystoplasmic proteins (Figure 111.2) The necrotic cell may have a more glassy homogenous appearance than that of normal cells, mainly as a result of the loss of glycogen particles. When enzymes have digested the cytoplasmic organelles, the cytoplasm becomes vacuolated and appears moth-eaten. Finally, calcification of the dead cells may occur. Dead cells may ultimately be replaced by large whorled phospholipid masses called myelin figures. These phospholipid precipitates are then either phagocytosed by other cells or further degraded into fatty acids; calcification of such fatty acid residues results in the generation of calcium soaps. Denatured proteins are observed under electron microscopy. Nuclear changes appear in the form karyokysis (fading of basophilia of the chromatin), pyknosis (nuclear shrinkage and increased basophilia, seen in apoptosis), and karyorrhexis (nuclear fragmentation) [26–29].

It is important to note that the morphologic appearance of coagulative necrosis is the result primarily of denaturation of intracellular proteins, and enzymatic digestion of the cell. The enzymes derive from the dead cells themselves, in which case the enzymatic digestion is referred to as *autolysis*; or from the lysosomes from migrating leukocytes, during inflammatory reactions. These processes require hours to develop and so there will be no detectable changes in cells immediately and 30 days after ablation [30, 31].

In addition, the temperatures created by RFA affect cellular metabolism and electrophysiology. The procedure causes microvascular and arteriolar occlusion, leading to ischemic changes in target tissues. This produces a predictable zone of coagulative necrosis that surrounds the ablative probe [30, 32].

Radiofrequency ablation

As discussed earlier, RFA involves the delivery of alternating current via monopolar or bipolar electrode to a target tissue with the intent to cause cell death. Radiofrequency energy can be introduced with a needle into tissue directly (dry RFA) or indirectly via ionic solutions (wet RFA) [33, 34]. The thermal tissue damage at high-temperature exposure can be predicted by means of the biophysical relationship in the Pennes Bioheat equation [35, 36].

The principles have been demonstrated in numerous *in vivo* studies: within defined temperature ranges, the thermal damage in tissue is approximately linearly dependent upon treatment time and exponentially dependent upon the increase in temperature. Accordingly, the Arrhenius analysis illustrates the variable sensitivity to heat exposure among different tissue types [37, 38]. The alternating electrical current is used to create resistive heating within the targeted tissue.

RF generators produce frequencies between 375 and 480 kHz, and power up to 250 W. The electrical energy is deposited in the tissue by means of a probe with a diameter of 1.6–2.5 mm insulated up to 2–5 cm in length [35]. In conventional "dry" monopolar RFA systems, the electrical circuit is established between the active applicator tip and one or several grounding pads, usually attached to the patient's thighs. The thermal heating is more intense close to the active needle tip, because of the narrow electrical streamlines, and has the highest current density. The highest tissue temperatures are reached at only a few millimeters surrounding the applicator tip, and via convective heating the resulting coagulative necrosis takes effect. In "dry" or conventional RFA, charring and tissue boiling close to the active needle tip increases impedance and therefore limits the zone of ablation. Goldberg *et al*. presented strategies to further increase induced coagulation necrosis, describing using multiprobe and bipolar arrays, and internally cooled radiofrequency electrodes, with or without pulsed-radiofrequency or cluster technique, and use of wet electrodes [36–38]. The development of these strategies allows for further increase of the coagulation diameter, while decreasing impedance.

Further increase of the coagulation diameter via augmenting the distance between the needles in the multi-applicator approach is not possible due to electrical shadowing in the center of the applicators [35]. Several overlapping ablations with intermittent repositioning of the applicator are performed for tumors greater than 3 cm. Pereira *et al.* directly compared the efficacy of per-

fusion, cooled-tip, nine- and 12-tine cluster electrodes in pig livers [39]. This group found that larger coagulation volumes were indeed created with the perfusion and cooled-tip electrodes. The multiple-tine devices created a more spherical lesion and were found to have better reproducibility. Bipolar and multipolar devices are now available [40], and used to achieve larger coagulation diameters and better-controlled energy deposition. Studies using some of these techniques have demonstrated ablation diameters of up to 7 cm with the placement of three applicators in a triangular fashion [41, 42]. With discovery and modifications in current technologies, the application of these principles continues to improve the efficacy and safety of RFA.

Radiofrequency ablation of renal tissue: experimental and histologic consideration

As described in the history of RFA above, thermal energy for target tissue destruction has been applied to the brain, bones, heart, lung, kidney, prostate, spleen, and liver. Several investigators have performed RFA for kidney in animal models and human studies [30–33, 43–47].

A number of investigators have undertaken the pathologic and histologic examination of the renal coagulation induced by RFA [30–33, 47–51]. Gross examination has revealed coagulation necrosis, which appears as a well-circumscribed blanched and yellowish–tan colored tissue. The histologic appearance on light microscopy reveals blurred nuclear chromatin, an increase in eosinophilia, loss of cell integrity, and presence of hemorrhage. Electron microscopy reveals prominent cytoplasmic granularity and near total loss of ultrastructural detail of the cytoplasmic organelles [35]. Within 2–4 weeks, the loss of cellular integrity occurs, as evidenced by nuclei lyses, cell membrane degeneration, and cellular fragmentation, and leads to coagulative necrosis in the ablated area. Tissue edema, inflammatory cells, neovascularization, and interstitial hemorrhage mark the inflammatory response around the coagulated area [30]. Microscopic and gross observations reveal distinct demarcation between the ablated renal tissue and the surrounding renal parenchyma. Investigators are able to distinguish four *zones of ablation* from the center to the periphery of the ablated renal lesion [48, 49]:

- Zone 1: carbonization occurs in the area of the renal lesion in direct proximity to the RFA probe;
- Zone 2: area of complete necrosis;
- Zone 3: area containing inflammatory cells and hemorrhage;
- Zone 4: normal renal parenchyma.

It is important to note that the tissue carbonization caused by the high temperatures used in RFA acts as a barrier to ablation (impedance), which investigators continue to work to overcome.

Over a few weeks to months, the ablated lesion shrinks due to absorption and fibrotic conversion of the coagulated lesion [32]. The histologic examination of the ablated lesion remains a subject of controversy. Corwin *et al*. evaluated the effectiveness of RFA in a porcine model using hilar occlusion techniques, and showed using nicotinamide adenine dinucleotide (NADH) staining that there were nonviable tissues after RFA. Marcovich *et al.* investigated and compared the histologic characteristics of RF-ablated porcine renal tissue using NADH and H&E staining [49]. The kidneys were immediately harvested, gross lesion size was measured, and tissue was processed for standard H&E and NADH staining. H&E staining of ablated tissue revealed a number of alterations in renal tubular histology. However, all of these findings were focal, with areas of parenchyma that appeared well preserved. Corresponding areas on NADH-processed sections showed the complete absence of staining, indicating the lack of cellular viability. There were no skip areas noted on NADH-processed sections and treated portions demonstrated a well-demarcated border of ablation. The authors concluded that while RFA produces discernible histologic changes acutely on H&E, these alterations are variable and patchy, and they alternate with areas of well-preserved tissue. In a recent study by Queiroz *et al*. to determine the efficient temperature for RFA of renal cells in a dog model, the authors indicated that H&E microscopic staining is optimal 14 days after RFA [50, 51]. Therefore, to assess and verify cellular death in RFA lesions, some authors recommend that NADH staining should be used [48], although this is not widely utilized because postablation biopsy is not routine.

Percutaneous radiofrequency ablation

McGovern *et al.* were the first to report the use of ultrasound guidance for RFA of renal tumors with the intent to treat [25]. The use of RFA as a treatment modality for renal tumors from its inception in 1999 to the present has paralleled the increased utility of NSS for indicated tumors; the main aim is to destroy the same volume of tissue that is usually removed with partial nephrectomy.

Bandi *et al*. determined the general trend in current practice of use of ablative technology for the management of SRMs at academic centers in the USA. An email survey was sent to 112 academic urologists subspecializing in minimally invasive ablative technology. Among the 62% of respondents, 93% of academic urology

centers used ablative technology, offering either cryoablation (79%) and/or RFA (55%) [52].

Indications

There is no randomized controlled trial comparing partial nephrectomy and RFA for the treatment of small renal masses. Most reports on percutaneous RFA are based on single-center retrospective studies. These studies indicate that RFA is an effective and safe treatment option for renal tumors in appropriately selected patients [44]. The use of percutaneous RFA as a strategy for treatment of SRMs has to be defined in the context of the overall clinical situation, including age and life-expectancy, radiologic assessment of local and distant disease burden, and patient compliance.

The indications for percutaneous RFA are similar to those for NSS [53], i.e. a contrast-enhancing SRM, T1a (<4 cm) or T1b (4–7 cm) (Table 111.1). Percutaneous RFA is effective generally in patients who have an absolute indication for NSS: synchronous bilateral renal masses, tumors in a solitary kidney, and presence of a poorly functioning contralateral renal unit. Percutaneous RFA is particularly effective and safe for patients harboring an SRM, with normal contralateral renal unit, and who are poor candidates for extirpative surgery.

The increased diagnosis of incidental renal masses in elderly patients with multiple medical comorbidities, including chronic renal insufficiency, requires a maximally nephron-conserving approach to management. Because up to 25% of SRMs are benign lesions with low metastatic potential [54–56], a conservative approach in the form of active surveillance or RFA has emerged for elderly patients who prefer proactive intervention.

Other indications for percutaneous RFA include RCC associated with familial renal cell carcinoma syndromes, i.e. von Hippel–Lindau (VHL) syndrome and hereditary papillary RCC presenting as multifocal lesions for which multiple partial nephrectomies might be cumbersome or impossible. Percutaneous RFA in patients with advanced or metastatic disease is primarily indicated to avoid rendering the patient anephric [57] and necessitating renal replacement therapy or dialysis. With primary tumor ablation, symptomatic relief may be possible while maintaining acceptable renal function. Overall survival has not been demonstrated for this indication in NSS or RFA; however, with the combination of radical nephrectomy and chemotherapy a slight increase in life-expectancy has been described [58]. Some authors suggest that complete ablation of renal tumors plus drug therapy may be a feasible option for carefully chosen candidates.

It is important to note that location and size of a renal tumor does not preclude the utility of percutaneous RFA. However, tumor size and location are strong predictors of ablation outcome in percutaneous RFA. With tumors less than 3 cm, complete ablation is achieved in most cases with one single session. In tumors greater than 5 cm repeated cycles may be required during a percutaneous RFA treatment to achieve the desired ablation outcome [59]. This applies for centrally located tumors that carry much lower ablation rates because of their proximity to the renal hilum, due to cooling effect of central blood vessels, the “heat sink” phenomenon [60]. The utility of percutaneous RFA is contingent on appropriate informed consent by patients willing to undertake this approach for tumor management.

Table 111.1 Indications for radiofrequency ablation.

Bilateral renal tumors
Multiple tumors in patients with VHL
Solitary kidneys will small renal mass (SRM)
Patients having SRM and renal impairment
Patients with SRM and not considered “fit for surgery”
Patient choice: SRM, when patient does not want surgery
Post partial nephrectomy local recurrence

Contraindications

Percutaneous RFA is best suited for posterior or laterally located tumors, but the presence of intestine or ureter within 1 cm of the ablation zone is a contraindication to this approach because thermal injury to these structures can occur (Table 111.2). Further contraindications include blockage of probe placement by intervening liver, spleen or lung. Problems may arise in tumors exhibiting large cystic components, as percutaneous RFA is less effective for cystic lesion. Finally, location immediately adjacent to the body wall or diaphragm is a relative contradiction because thermal injury to the musculature and nervous structures can lead to increased postoperative pain. Laparoscopic RFA is best

Table 111.2 Contraindications to radiofrequency ablation.

Absolute contraindications
Uncontrolled bleeding diathesis
Relative contraindications
• Patients on anticoagulation: needs correction before procedure
• Confounding anatomic factors:
Pleura open up after positioning
Proximity of bowel, ureter or adrenal gland
Cystic tumors
Obvious proximity to large vessels
• Technology: absence of good imaging/multislice CT
• Surgeon factors: inexperienced operator

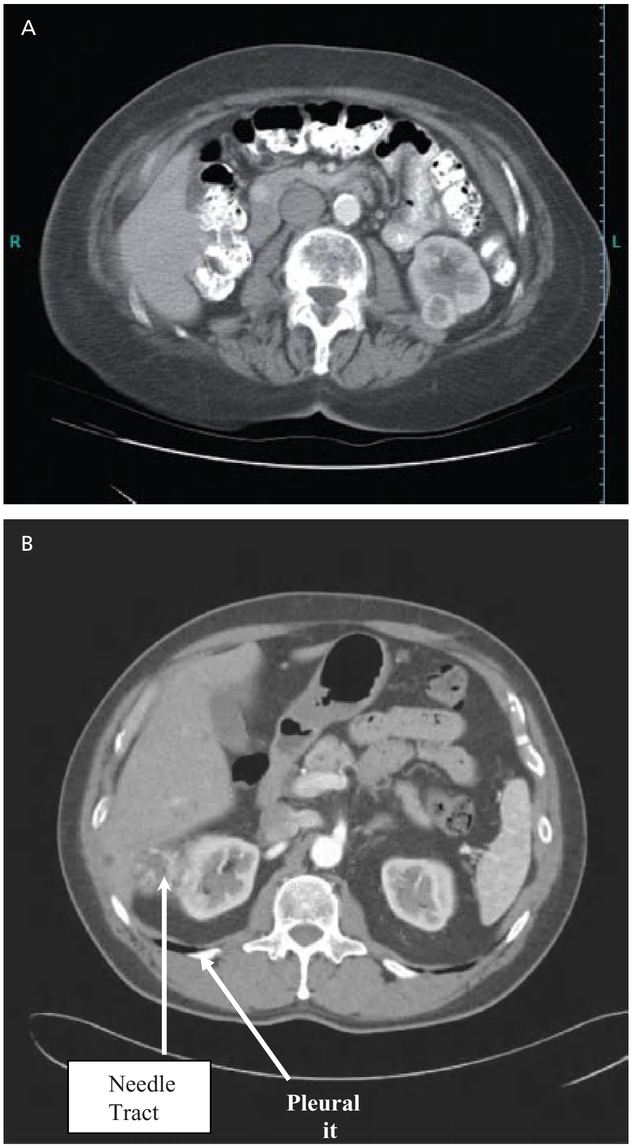

Figure 111.3 Preoperative evaluation. (A) Preablation contrast-enhanced CT scan showing a posterior solid enhancing renal mass. This location is ideal for CT-guided radiofrequency ablation. (B) Inferior extent of pleural cavity visible at mid portion of right-sided tumor. Extra caution must be used to avoid transpleural puncture. Options include oblique needle placement or transhepatic percutaneous placement. Laparoscopic exposure would also be a safe alternative.

suited for anterior or medially located tumors as this allows for laparoscopic mobilization of the bowel, exposure of the tumor surface, and direct visualization of insertion of the ablation probe into the tumor parenchyma for efficacy and safety. Laparoscopic exposure reduces the risk of thermal injury to adjacent organs. In addition to intestinal mobilization and protection, laparoscopic approaches allow separation of other vital structures, including the ureter and renal pelvis from

Table 111.3 Comparison of ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) modalities in radiofrequency ablation (adapted from Leveillee and Ramanathan [61]).

	Ultrasound	CT	MRI
Pretreatment assessment	Good	Excellent	Excellent
Probe placement	Good	Excellent	Excellent
Temperature monitoring	Not possible	CT thermography possible	MR thermometry possible
Monitoring of ablation	Imaging deterioration occurs	Possible	Possible
Needle relocation	Technically difficult due to image deterioration	Possible	Possible
Realtime imaging	Possible	Difficult	Difficult
Radiation exposure	No	Yes	No

Table 111.4 Four-stage process to be completed prior to radiofrequency ablation.

Stage 1	*Preoperative assessment* Preoperative imaging and treatment planning
Stage 2	*Intraoperative assessment* Imaging, planning, and targeting

the ablation zone. We have not experienced thermal damage to the ureter, renal pelvis, vasculature, or bowel when diligent dissection and mobilization was performed (Figure 111.3).

Technique and modalities

Percutaneous RFA can be performed with one the following methods of image guidance: CT, magnetic resonance imaging (MRI) or ultrasound (Table 111.3).

A four-stage process should be initiated prior to RFA to ensure successful treatment at the time of ablation [61] (Table 111.4). Prior to intervention, a thorough

Table 111.5 Radiofrequency ablation devices.

LeVeen System	RITA system	Cool Tip™ system

history and physical examination of the patient is completed. A CT renal mass protocol is used to delineate the renal tumor prior to ablation. MRI with gadolinium enhancement is an alternative for patients with renal insufficiency [glomerular filtration rate (GFR) > 30 mL/min/1.73 m^2). Laboratory values are obtained, including a coagulation panel, and a well-written informed consent to treatment is obtained from the patient.

A CT renal mass protocol is used to delineate the renal tumor prior to ablation. MRI with gadolinium enhancement is an alternative for patients with renal insufficiency who have a GFR greater than 30 mL/min/1.73 m^2). After the team has reviewed the preoperative imaging, the probe type, location, and circuit type are determined based on tumor characteristics, size, and anatomic relation to other structures. A collaborative and coordinated effort between the urologist, interventional radiologist, anesthesiologist, surgical nurse, and technician is essential to successful treatment of the patient [61].

Prior to the procedure, the urologist and, or interventional radiologist must decide on the type of RFA device used. In the USA, there are three monopolar systems capable of delivering up to 250 W of power (Table 111.5):
- Cool Tip™ RF system (Covidien, Boulder, CO, USA);
- LeVeen RF system (Boston Scientific, Natick, MA, USA);
- RITA RF system (Angiodynamics, Queensbury, NY, USA).

The different RFA devices involve either temperature or impedance feedback loops, in which the generators modulate the amount of electrical current delivered to the probe. The heating of renal lesions varies with the amount of current delivered to the lesion; too much electrical energy delivered to the tissue causes charring around the electrode, therefore impeding complete tumor ablation. To prevent this problem, RF generators control the amount of power delivered to the probe based on either temperature or impedance feedback from the probe and manufacturers' algorithms [62].

RF probes are either single- or multi-tined probes and cooled tip probes. The use of multiple tines has the theoretical advantage of spreading electrical current over a larger area, creating a larger zone of ablation without charring around the probe. The Cool Tip™ electrode (Covidien) is a single-prong electrode that circulates saline or other liquid coolant within the electrode to decrease the temperature of the probe and the immediate surrounding tissue. This prevents charring around the probe and allows more energy to be delivered into the tumor.

Percutaneous RFA is carried out under general anesthesia or conscious sedation. Some investigators (including us) advocate the use the use of general anesthesia when possible, which is thought to optimize patient tolerance; allow for greater respiratory control during probe placement, improving targeting to tumor; and potentially give a better outcome [63]. Intravenous sedation offers the advantage of decreased morbidity from general anesthesia and the ability to perform RFA as an outpatient only procedure. Gupta *et al*. presented outcomes of percutaneous RFA of 163 renal tumors in 151 patients who underwent general anesthesia prior to ablation [63]. Comparison of their series with other series using intravenous sedation showed initial complete ablation rates were higher in the general anesthesia series than in the conscious sedation series. However, the authors caution the interpretation of these findings given the heterogeneity in eligibility criteria, variation in technique, definition of incomplete ablation, methodology of data analysis, and presentation of results. As such, there is insufficient evidence in the literature to advocate use of one method of anesthesia over another.

Probe placement of RF needles is accomplished under ultrasound, CT, or MRI guidance. In published data, most authors prefer CT guidance, which is used in over 70% of percutaneous RFAs performed in the USA [52]. Some high-volume centers perform percutaneous RFA efficiently with excellent results using conscious sedation and other forms of image guidance [52, 59, 64–71].

Image guidance with CT is performed with or without intravenous contrast. The use of intravenous contrast helps to accurately image the lesion in question. Accurate identification of the tumor and other structures (spleen, liver, bowel, lung, and surrounding pleura) is essential in planning percutaneous access to the lesion. Several methods of bowel manipulation have been described and continue to be refined to increase the separation between vital structures and the renal lesion.

The patient is placed in a prone or full flank position (Figures 111.4 and 111.5) to provide percutaneous access to the retroperitoneum. If peripheral temperature monitoring is performed, two to three fiberoptic temperature sensors (LumaSense, Santa Clara, CA, USA) are placed

Figure 111.4 Patient positioning for CT-guided radiofrequency ablation.

Figure 111.5 Localization grid with patient in prone position (A) outside and (B) under the CT scanner.

under CT guidance (or other choice of imaging modality) at the peripheral (superior, inferior, lateral, and medial) and deep margins of the tumor, 5 mm from the tumor–parenchyma interface (Figures 111.6–111.9).

Nonconducting 18G sheaths are placed (TLA or Yueh) and the probes are then inserted via the sheaths. Prior to ablation, biopsies of the tumor are obtained with a spring-loaded (i.e. Tru-Cut) biopsy needle to obtain a diagnosis (see Chapter 110). A frozen section may or may not be requested (we do not).

It is not routine to use intravenous contrast during CT-guided ablation if preoperative imaging is done with contrast and demonstrates a well-defined tumor border. Injection of contrast can only be performed once per ablation session because it requires several hours for clearance.

The probes are positioned under CT guidance percutaneously, directed toward the center of the tumor, and advanced until the deep margin is reached with the probe tip (Figures 111.7 and 111.8). If expandable ablation needles are used, these are deployed according to the manufacturer's algorithm. Positioning of the ablation needle is performed and RFA is initiated. Complete ablation is achieved at a specific time interval, at which point a "target temperature" or impedance is reached at the probe tip or the peripheral temperature monitors, i.e. when all "target temperatures" have been achieved at the tumor margins (>5 mm, 60°C). To achieve the optimal temperature, manipulation and alternate targeting of the RF probes and repeat application of radiofrequency energy is necessary [72] (see Video 111.1).

MRI-guided RFA has been used by various authors as the imaging modality of choice [73–75]. The delivery of radiofrequency energy is performed using custom-manufactured MRI-compatible "cooled-tip" radiofrequency probes using a temperature-controlled system. According to Lewin *et al.*, single or multiple ablation cycles of 12–15 min at 90°C are applied until the entire tumor is replaced by a zone with low signal intensity on T2-weighted and/or short inversion time inversion-recovery images [73]. This allows for "realtime" monitoring of ablation. MRI on T2-weighted images demonstrates clear postablation changes that appear to be reproducible [76]. In the acute phase after ablation, the hypointense area of complete necrosis is typically surrounded by a small hyperintense rim, which corresponds to the zone of inflammation and hemorrhage. Residual tumor tissue can be detected due to its persisting isointense or hyperintense signal. The area(s) of incomplete treatment is further ablated with repositioning of the probe. Subsequent RFA can be performed multiple times during the same session, which allows for repeated assessment of ablation outcome using MRI without injection of contrast. This provides an added advantage over all the other imaging modalities. The success rates of complete tumor ablation are comparable to CT-guided ablation at 92–100% of cases within one single session [72].

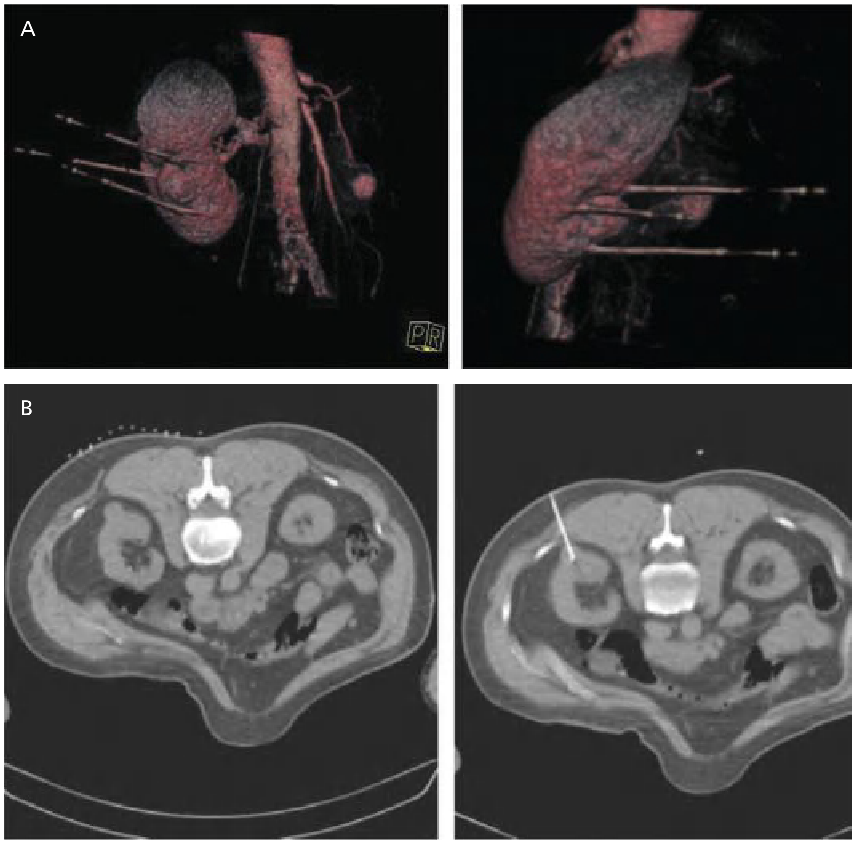

Figure 111.6 (A) Three-dimensional reconstruction of peripheral temperature monitoring guide needles. (B) Ablation needle placement through right posterior tumor center (prone position).

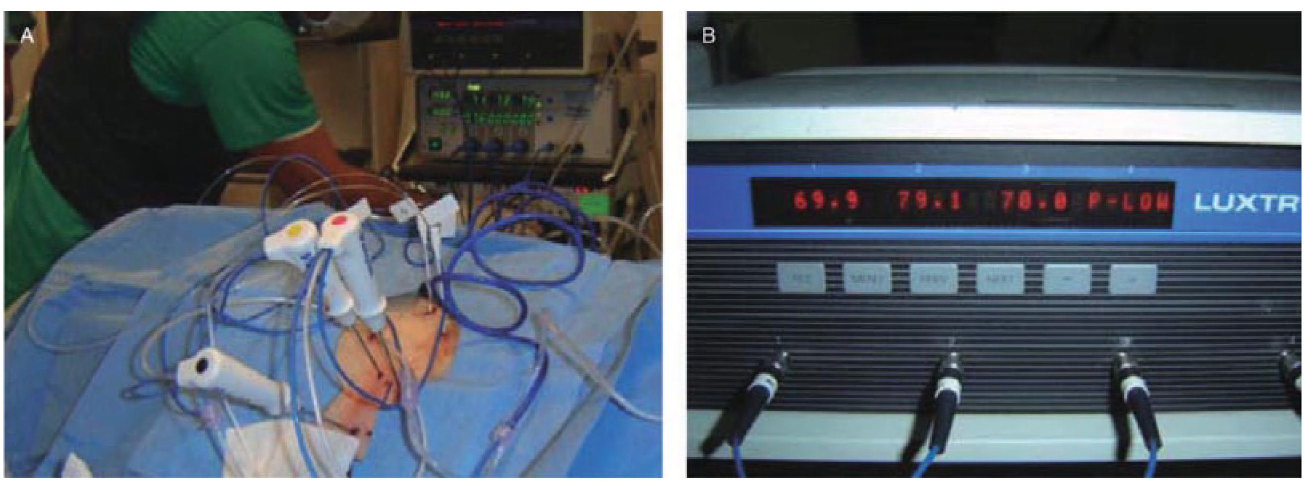

Figure 111.7 Realtime temperature monitoring performed through fiberoptic monitors; ablation is complete when all temperatures exceed 60°C.

Ultrasound-guided ablation is the least used modality in the treatment of renal lesions with radiofrequency energy. The production of gas bubbles by vaporization during the procedure significantly disturbs image quality due to hyperechogeneity [35]. While investigators continue to explore ways to improve ultrasound-guided RFA [40], in light of inherent limitations of CT and MRI guidance [77], its use remains limited and requires further evaluation.

Outcomes/results

The use of ablative therapy for SRM management is accepted as primary treatment for patients with comorbidities who are poor candidates for surgical resection. The promising outcomes from various centers have led many investigators, including us, to encourage the use of needle ablative therapy in healthy, younger patients. Local eradication of the tumor is the primary aim of treatment. There is significant controversy regarding the definition of success. The Working Group on Image-Guided Tumor Ablation defined successful ablation as completely treated renal mass with no residual tumor left behind [78–80]. The American Urological Association when drafting its guidelines for the treatment of SRM used a very strict definition, "For the ablation studies, local recurrence was defined as any localized disease remaining in the treated kidney at any point after the first ablation treatment."

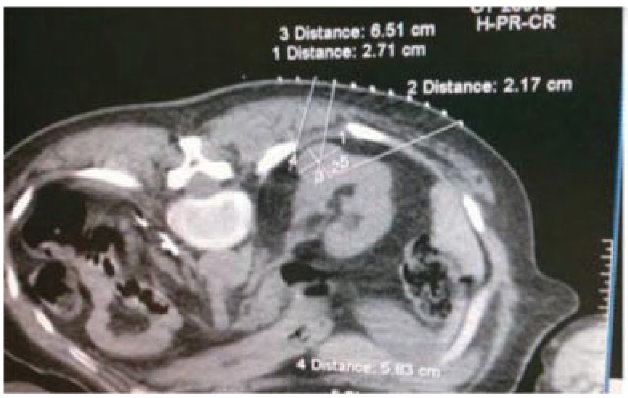

Figure 111.8 Planning with markers and targeting depicted on a noncontrast CT scan.

The initial success of percutaneous RFA in the treatment of RCC has led to its increased use in patients who opt to undergo minimally invasive treatment. With well-defined, short-term efficacy, intermediate and long-term cancer control rates for this emerging technology are becoming more available and the results continue to be very encouraging (Table 111.6).

Levinson *et al*. reviewed the overall oncologic and survival outcomes in patients with a solitary renal mass treated using RFA at follow-up of at least 40 months [81]. Patients were offered RFA due to the high risk of surgical management and surgeon preference. Follow-up consisted of serum creatinine measurement, physical examination, and serial contrast-enhanced CT or MRI. The 31 patients received a total of 34 RFA treatments to a 1.0–4.0-cm solitary renal mass (median 2.0 cm). Mean follow-up in survivors was 61.6 months (median 62.4 months, range 41–80 months). There was one primary treatment failure, which was successfully retreated, and three recurrences at 7, 13, and 31 months after RFA, respectively. The overall recurrence-free survival rate

was 90.3%. There was a 100% metastasis-free and disease-specific survival rate in the cohort. Overall patient survival was 71.0% since nine died of non-RCC causes. Of the 31 patients, 18 had pathologically-confirmed RCC. In these 18 cases, the actuarial disease-specific, metastasis-free, recurrence-free and overall survival rates were 100%, 100%, 79.9%, and 58.3%, respectively, at a mean of 57.4 months of follow-up. In the entire cohort the difference between the pretreatment and the last known serum creatinine level was 0.15 mg/dL ($P = .06$). The authors concluded that in patients who have limited life-expectancy or are high-risk surgical candidates, RFA provides reasonable long-term oncologic control and it may have a role in the management of SRMs.

Tracy *et al.* presented one of the largest series to date evaluating the long-term oncologic outcome after RF ablation for small renal tumors [82]. The authors report their experience with RFA of SRMs in the management of 208 patients (with 243 tumors) over the past 7.5 years, with particular attention to 66 patients (with 84 tumors) who had a documented radiographic follow-up of at least 3 years. The initial treatment success rate was 97%, and the overall 5-year recurrence-free survival rate was 93% (90% for 160 patients who had biopsy-proven RCC). During follow-up, three patients developed metastatic disease, and one died of RCC, yielding 5-year actuarial metastasis-free and cancer-specific survival rates of 95% and 99%, respectively.

In addition to strengthening the current intermediate-term evidence of RFA efficacy, these results appear to compare favorably with those for cryoablation of SRMs. In the longest detailed follow-up study available for cryoablation, Aron *et al*. reported 5-year overall, disease-specific ,and disease-free survival rates of 84%, 92%, and 81%, and 10-year rates of 51%, 83%, and 78%, respectively [83]. These data are comparable to the most recently published reports on RFA, with rates of 93%, 99%, and 85%, respectively for 5-year follow-up [82]. It is important to note that in the RFA series, 71% of the tumors were treated percutaneously, while the approach in 100% of the cryoablation series was laparoscopic.

The radiofrequency technology was embraced by interventional radiologists, whereas cryoablation delivered laparoscopically seems to have been accepted early by surgeons, despite minimal evidence to support its superiority. The major attraction in favor of freezing techniques has long been the visualization of the targeted "ice ball" and reduction in tumor diameter in follow-up imaging. It must be remembered, however, that these two ablative techniques manifest their effect through entirely different mechanisms and cannot be easily compared head-to-head. Another important point of distinction is the *intent-to-treat* in earlier series by interventional radiologist or urologists, which during initial experience led to repeat ablations. The results when later interpreted showed a "perceived" increased recurrence compared to cryoablation.

Renal functional outcome

RFA is advocated in patients with multiple comorbidities who are poor surgical candidates. Inherent in these patients is a baseline renal insufficiency, all of whom have some degree of CKD. RFA gives the opportunity to obviate the need for hilar clamping and ischemia, and is an alternative for patients with baseline renal dysfunction. Numerous investigators have sought to define the renal functional outcome in patients undergoing definitive RFA of renal tumors [81, 84–91].

Using the Modification of Diet and Renal Disease equation, Raman *et al.* calculated and compared the median GFR change in 47 patients with a solitary kidney after RFA to 42 patients undergoing open partial

nephrectomy (OPN) [89]. The median age (65.9 vs 59.6 years, $P = .03$) and American Society of Anesthesiology score (3.0 vs 2.0, $P = .01$) were both higher in the patients treated with RFA. The median tumor size was greater for tumors managed by OPN (3.9 vs. 2.8 cm, $P = .001$), while the median preoperative was lower in the RFA group (46.5 vs 55.9 mL/min/1.73 m^2 for OPN, $P = .04$). Compared to RFA, patients treated with OPN had a greater decline in GFR at all times evaluated, including soon after the procedure (15.8% vs 7.1%), 12 months after surgery (24.5% vs 10.4%) and at the last follow-up (28.6% vs 11.4%, all $P < .001$). For patients with a pretreatment GFR of greater than 60 or less than 30 mL/min/1.73 m^2, there was a new onset of decline in GFR of less than 60 and less than 30 mL/min/1.73 m^2 in 0% and 7% of patients after RFA, and in 35% and 17% after OPN. The authors concluded that RFA may obviate ischemic insults, and is favorable option for managing tumors in solitary kidneys at risk of declining function [89].

In a landmark study, Lucas *et al*. evaluated renal functional outcome of 242 consecutive patients from July 1995 to March 2005 undergoing primary treatment for unilateral renal masses smaller than 4 cm and a normal contralateral kidney [92]. Renal function was calculated using the modified Modification of Diet in Renal Disease equation. The rate of decrease in the GFR below 60 mL/min/1.73 m^2 was compared among three treatment arms: 86, 85, and 71 patients were treated with RFA, partial nephrectomy, and radical nephrectomy, respectively. Preoperatively stage 3 CKD (GFR < 60 mL/min/1.73 m^2) was identified in 65 patients (26.7%), including 26.7%, 27.1%, and 26.8% of those who underwent RFA, partial nephrectomy, and radical nephrectomy, respectively. Following intervention, the 3-year freedom from a GFR decrease of below 60 mL/min/1.73 m^2 for RFA, partial nephrectomy, and radical nephrectomy was 95.2%, 70.7%, and 39.9%, respectively ($P < .001$). Multivariate analysis showed that radical nephrectomy was an independent risk factor versus RFA and partial nephrectomy for stage 3 CKD (HR 34.3, 95% CI 4.28–275 and 10.9, 95% CI 1.36–88.7, respectively). The authors concluded that decreased renal function is prevalent in patients with SRMs, even those with a normal contralateral kidney, and ablative or extirpative nephron-sparing techniques are effective for preserving renal function in these patients. These data suggest that RFA provides the lowest rate of renal impairment, which can be attributed to the lack of vascular clamping used in extirpative NSS.

Complications and strategies for their prevention

Complications described with RFA include hemorrhage requiring blood transfusion (2.3%) [59]; abscess formation mimicking tumor recurrence [93]; ureteral strictures, ureteropelvic junction obstruction, and delayed hemorrhage [94]; reno-colic fistula [95]; renoduodenal fistula [96]; and neuromuscular complications [97] with paresthesia in the distribution of the genitofemoral nerve when ablating lesions near the psoas muscle. Treatment of central tumors is most likely to cause hematuria, which is usually self-limiting [86].

Ablating the probe track during removal minimizes the likelihood of tumor seeding along it after biopsy or ablation [98].

Many of the above complications are related to proximity of the tumor to neighboring organs [99]. In order to avoid many of them, the distance between the tumor and neighboring organs may be increased artificially by using methods such as changing the patient's position, using the radiofrequency electrode as a lever, and hydrodissection [99] . A postablation CT is useful in identifying the presence of a pneumothorax or perirenal hematoma.

Follow-up after ablation

Patient follow-up should include adequate history, physical examination, chest X-ray, creatinine, and contrast-enhanced CT or MRI studies at specified intervals (see below). Our standardized follow-up protocol is given in Table 111.7.

Conclusions

Although long-term data are being accumulated, multiple and recent series continue to demonstrate near

Table 111.7 Follow-up protocol.

1–3 months	CT scan: renal mass protocol (Figure 111.10)
6 months	CT scan: renal mass protocol Chest X-ray
Annually thereafter × 4	CT scan: renal mass protocol Chest X-ray Liver function tests (LFTs)
Thereafter × 5	CT scan: renal mass protocol Annual Chest X-ray Annual LFTs

Dedicated chest CT with/without contrast if any suspicious lesions on chest X-ray or upper cuts of CT abdomen.
Bone scan/dedicated radiographs if suspected lesions.
Suspicious lesions may need to be biopsied (laparoscopic, VATS-guided or percutaneous image-guided).
Incomplete ablation is defined as persistent quantifiable contrast enhancement at any point greater than 1 month after initial ablation. Although the definition of recurrence remains controversial, we define recurrence as contrast enhancement after at least 6 months.

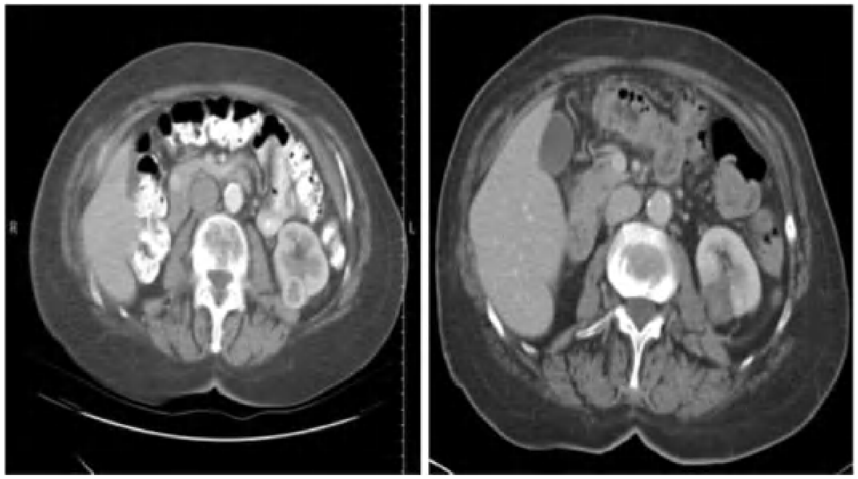

Figure 111.10 Post radiofrequency ablation surveillance CT scan at 1–3 month follow-up.

equivalent oncologic outcomes when RFA is compared to extirpative surgeries for SRMs. The added benefit of minimal invasiveness and renal function preservation continues to make RFA increasingly popular for definitive management of appropriately selected tumors and patients.

CHAPTER 112

Percutaneous Cryoablation for Renal Tumors

Manish A. Vira

Hofstra University School of Medicine, The Arthur Smith Institute for Urology, North Shore – LIJ Health System, New Hyde Park, NY, USA

Introduction

In 2009 there were an estimated 57 670 new cases of kidney cancer in the USA alone [1]. The majority of these tumors are confined to the kidney and therefore amenable to curative treatments. Historically, radical nephrectomy had been the treatment of choice, demonstrating excellent oncologic efficacy. However, with the recognition of the long-term adverse affect of renal loss on patient comorbidities, a nephron-sparing approach became the standard of care, particularly for tumors of less than 4 cm in size. The first laparoscopic nephrectomy in 1991 ushered in minimally invasive approaches to the treatment of kidney cancer, allowing patients to avoid the significant morbidity and recuperation of a flank incision [2]. The minimally invasive approach has evolved into complex laparoscopic partial nephrectomy and laparoendoscopic single-site surgery. With the intent of further reducing both the morbidity of treatment and minimizing damage to the remaining renal parenchyma, urologists introduced cryosurgery for the treatment of renal lesions in the 1990s [3, 4]. Subsequent series established feasibility and safety of cryoablation for small renal masses [5, 6]. Although the early cohorts of patients were treated via a laparoscopy-assisted approach, percutaneous cryoablation has become an acceptable alternative to the surgical excision of small renal tumors. This chapter will review the evolution, cryobiology, indications, technique, results, and complications of percutaneous cryoablation.

Evolution of cryotherapy as a cancer treatment

The concept of cryosurgery is not new and can be traced back to the mid 1800s when Dr Arnott first published his observations when using cold therapy to treat accessible advanced tumors [7]. He reported a decrease in the size of the tumors with reduction in drainage and pain. His method was displayed at the Great Exhibition in London [8]. From Dr Arnott's early work, interest in thermal therapy in the treatment of a variety of oncologic, dermatologic, and epithelial conditions grew, but was limited by the available technology. The first major advance was the commercial introduction of liquid nitrogen, which facilitated freezing to temperatures of –196°C [9]. The subsequent addition of copper cylinder discs immersed in liquid nitrogen allowed for greater tissue penetration, resulting in ablation depths of 4–5 mm as compared to 1–2 mm with carbon dioxide-based techniques [8]. Through the 1940s and 1950s, cryosurgery gained little attention primarily due to the limitation in technology, and research focused more on understanding the pathophysiology of cryoablation.

The next major breakthrough, which ushered the era of modern cryosurgery, was introduced by Cooper and Lee, who together developed an apparatus for automated circulation of liquid nitrogen within a cannula that could be inserted to ablate the basal ganglia in the treatment of involuntary movement disorders [10].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Subsequent applications included ablation of pituitary tumors in patients with acromegaly [11].

Through the 1960s to the early 1980s, experience, interest, and instrumentation advanced, and cryosurgery expanded into urology in the treatment of the prostate (both benign and malignant), gynecology for inoperative cervical and uterine tumors, and ophthalmology for a variety of eye conditions. With the application of the Joule–Thomson effect, additional cryogens (including carbon dioxide and argon compressed gas) were available, resulting in the development of diverse instrumentation and smaller probes. Interest in cryosurgery began to wane in the early 1980s as other forms of treatment became favored and advances in cryosurgical instruments slowed.

The 1990s began the next resurgence of cryosurgical techniques as a result of three primary factors. First, endoscopic and laparoscopic instruments improved, facilitating the explosion of minimally invasive surgery. Second, next-generation cryosurgical devices cooled to lower temperatures, resulting in more reliable ablation, and vacuum-insulated probes became smaller in diameter. Finally and perhaps most importantly, the introduction of intraoperative ultrasound facilitated realtime monitoring of the ice balls, allowing for accurate and complete treatment of target lesions [12, 13]. More recently, integration of sophisticated realtime imaging techniques, including computed tomography (CT) and magnetic resonance imaging (MRI) into the surgical and interventional suite has resulted in the ability to percutaneously cryoablate target lesions in more difficult locations with less risk to surrounding tissues.

Mechanism of action

As early as the 1960s, it was recognized that one of the primary mechanisms of cryotherapy-induced cell death was direct injury secondary to intracellular and extracellular ice formation [14]. Intracellular ice formation occurs in close vicinity to the cryoprobe secondary to rapid cooling temperature changes. The rapid cooling results in intracellular freezing before water can diffuse out of the cell. Intracellular ice crystals can also develop at temperatures lower than −20°C regardless of the cooling rate. Although not well understood, intracellular ice crystals are thought to mechanically disrupt the nucleus and organelles, resulting in cell dysfunction and death. Recent studies suggest that mitochondrial injury from intracellular crystals may induce cellular apoptosis [15]. Further away from the probe where cooling rates are slower and minimum temperature is higher (between 0°C and −20°C), the bulk of direct cellular injury appears to occur through formation of extracellular ice crystals. The crystallization of the extracellular environment results in dramatically increased solute concentrations driving water across the cell membrane into the surrounding spaces. The cells then become osmotically dehydrated, causing disruption of the cellular membrane and breakdown of the protein machinery [16].

The degree of direct cell injury during the acute phase is affected by several thermal parameters, including the rate of cooling, minimum temperature achieved, duration of freeze, and rate of thaw [17]. Most *in vitro* studies show that rapid cooling rates achieve a higher degree of cell death; however, cooling rates *in vivo* can vary widely depending on the instrumentation and the properties of the target tissue. In reality, rapid cooling (>50°C/min) likely occurs only in close proximity to the cryoprobe. Therefore, given the variability in cooling rates, it is more important to achieve minimum temperature thresholds throughout the target tissue. Tatsutani *et al.* sought to quantify the relationship between thermal variables and cell destruction in prostate adenocarcinoma cell lines [18]. Their results indicated that for slower cooling rates, complete cell ablation was achieved by reaching a threshold of −40°C. The duration of freeze becomes a factor in the zones where the minimal temperature threshold is not achieved. In these areas with a temperature between 0°C and −40°C, longer durations allow for more complete osmotic dehydration of the cells as extracellular crystallization occurs. Finally, slow and complete thawing in between freeze cycles is recognized as a critical factor in achieving maximal cell ablation. Slow thaw facilitates cell injury by maximizing the increased extracellular solute effects and recrystallization (the process by which crystals fuse to form larger, more destructive crystals).

The second mechanism of cell death in cryotherapy is delayed tissue ablation secondary to changes in the microvasculature of the target tissue. The pathophysiology of delayed injury was first recognized by investigators studying the effects of frostbite and the resultant vascular changes [19]. The constellation of changes leading to tissue ablation occurs during both freeze and thaw. During the initial freeze, vascular flow ceases, resulting in hypoxia and direct cell injury. During the subsequent thaw, the tissue responds with a compensatory vasodilation and hyperemia. However, the cryotherapy-induced damage to the endothelial and microvessel wall results in increased capillary wall permeability, interstitial edema, platelet aggregation, and formation of the microthrombi [16]. The loss of endothelial cell junctions can be seen as early as 2 h after a freeze–thaw cycle [20]. Most small vessels are thrombosed by 4 h, with larger vessels by 24 h. Together the changes result in widespread tissue ischemia, tissue necrosis, and eventual scar formation. Although it is

difficult to measure the relative impact of direct cell injury (acute) versus vascular injury (delayed), most investigators suggest that the latter may be the more important factor in complete tissue cryoablation.

Since the beginning of modern cryosurgery, it has been recognized that repeated freeze–thaw cycles are critical to maximize cell destruction in the zone of ablation [21]. Chua and Ho developed an analytical model to simulate the effect of multiple freezing parameters on the efficacy of cryoablation and reported that a second freeze–thaw cycle may increase cell death by 50% as compared to a single cycle [22]. The improvement in cell death is seen at the periphery of the ablation zone where minimum temperatures may only reach –20°C to –30°C. Histologic studies in animals undergoing experimental cryosurgery have demonstrated that the second cycle increases the size of the ablation zone and enhances cell destruction [23–25].

In an effort to enhance the lethality of cryosurgery, recent investigations have focused on other mechanisms of cryo-induced cell death, including direct cell injury-induced apoptosis and the immunologic response. Grdovic *et al*. studied apoptosis pathways in liver tissue and found multiple products of apoptotic activation in the cytosol of cells in the ablation zone [26]. Wen *et al*. performed cryotherapy of lung adenocarcinoma implants in mice and found cell necrosis due to direct cell injury in the central zone of the tumor and activation of caspase 3 and poly-ADP ribose polymerase (PARP) in the peripheral zone [15]. They concluded that apoptotic pathways are more important in the peripheral zone of ablation where temperatures do not meet necrotic thresholds. With regards to the immunologic response, substantial infiltration by immune cells is seen after cryotherapy. However, there has been conflicting evidence regarding the impact of these immune cells on cell death [17]. More recent studies have focused on the potential of immunomodulation to augment cell death. For example, Jiang *et al*. and Clarke *et al*. reported enhanced lethality of cryoablation when combined with tumor necrosis factor-alpha (TNF-α) and TNF-related apoptosis-inducing ligand (TRAIL) [27, 28].

Indications and contraindications for percutaneous cryoablation

During the early experience, percutaneous cryoablation was reserved for small peripheral kidney tumors [4, 29]. However, improved interventional imaging and more experience have allowed expansion of indications to include tumors in more complex locations, including perihilar, endophytic, and neighboring adjacent organs. Although there are no specific size criteria, percutaneous ablation is generally indicated for tumors less than 4cm in greatest diameter. Several studies have shown increased complication rates with larger tumors. Most urologists prefer the percutaneous approach for patients with significant comorbidities who may not be surgical candidates.

The contraindications for percutaneous ablation can be grouped into tumor-related and patient-related factors. Absolute tumor-related complications include tumors with vein thrombus, tumors with adjacent organ invasion, and tumors not safely accessible via percutaneous approach. Relative tumor-related contraindications include tumors larger than 3–4cm, centrally located tumors, and tumors radiographically adjacent to neighboring organs (especially in previously operated upon kidneys). Absolute patient-related contraindications include uncorrectable bleeding diathesis, morbid obesity (unable to fit CT or MRI gantry), and severe medical comorbidity that limits the patient's ability to lie flat in the prone position. Relative patient-related contraindications include young age, hereditary kidney cancer syndromes (in which future kidney surgery may be anticipated), correctable bleeding diathesis, and solitary kidney.

Technique

Patient selection and preoperative evaluation

As with any surgical procedure, appropriate patient selection is a precursor for successful outcomes. Patients most suitable for percutaneous ablation are those with renal insufficiency, prior renal surgery, or medical comorbidity that increases risk of general anesthesia and surgery. Although some clinicians reserve ablation for elderly patients (>70 years old), we feel that age should be a relative factor in the recommendation for ablation. For example, we have offered percutaneous ablation even in younger patients (50–70 years old) with small, indeterminate lesions who are seeking definitive intervention. We strongly advocate the joint evaluation and participation by both the urologist and interventional radiologist. Patients should undergo routine presurgical testing, including complete blood count, basic metabolic panel, chest X-ray, and electrocardiogram. Coagulation studies are generally only required in patients with known or suspected bleeding diathesis. Most patients undergo the procedure under conscious sedation or monitored anesthesia care. However, patients with pulmonary disease may require general anesthesia with intubation and therefore, should undergo appropriate preprocedure pulmonary and anesthesia evaluation. Patients with intravenous contrast allergy should be prepped with prednisone and diphenhydramine in case contrast is necessary to image the lesion during probe placement.

Preoperative or concomitant biopsy

The role of percutaneous biopsy of kidney lesions has long been controversial. The emergence of active surveillance and percutaneous ablation has increased enthusiasm and more importantly, reinvigorated research in improving the value of biopsy (see Chapter 110). Historically, fine needle aspiration (FNA) biopsy suffered from a combination of low sensitivity and high false-negative rates. In a recent review, Volpe *et al*. found that large series of FNA biopsies reported sensitivity of 76–97% and nondiagnostic rates of 7–24% [30]. Core biopsies clearly improve on the accuracy of percutaneous biopsy, as demonstrated by two recent series. Wang *et al.* performed core biopsies on 110 patients and reported a sensitivity of 90.1% with histopathologic accuracy in 100% of the 34 patients who ultimately went on to extirpation [31]. Volpe *et al*. performed ultrasound/CT-guided core biopsies on 100 patients and reported 84% sensitivity and again 100% histopathologic accuracy in 20 patients who underwent subsequent extirpation [32]. Furthermore, histologic subtyping and grading was possible in 93% and 63%, respectively. The primary hesitation in performing more core biopsies is the concern for complications; however, the recent literature reports risk of tumor seeding as 0.01%, significant retroperitoneal hematoma as less than 2%, and mortality as 0.031% [30, 31]. With regards to percutaneous ablation, pathologic confirmation is useful in following patients post procedure, especially in the circumstance of imaging findings of recurrence. In addition, a biopsy will reveal less common diagnoses, such as sarcoma, renal lymphoma, or metastasis. As such, we feel that percutaneous biopsy by either core or FNA should be performed either prior to or at the time of percutaneous cryoablation. The recommendations of the Society of Interventional Radiology echo this statement [33].

Image guidance and probe placement

Percutaneous cryoablation of renal tumors can be performed under ultrasound, CT, or MRI guidance. All three modalities allow for accurate needle or probe placement for ablation. Ultrasound has the advantage for true realtime needle and probe placement. However, percutaneous monitoring of the ice ball is compromised due to acoustic shadowing from the advancing ice ball. Furthermore, tumors in complex locations, such as adjacent to neighboring bowel, are not suited for ultrasound guidance as the proximity of the adjacent structures is not readily evident sonographically. Some practitioners use ultrasound for initial probe placement; however, by far the most commonly used imaging modality for precise placement and monitoring during percutaneous cryoablation is CT scan. Its advantages include excellent anatomic resolution, reasonable monitoring of the ice ball, and opportunity for post probe removal imaging to detect significant bleeding complications. The disadvantages include the associated radiation exposure, inability to visualize certain endophytic lesions without intravenous contrast, and the lack of realtime imaging. The latter disadvantage could be overcome with the use of CT fluoroscopy; however, its widespread use is limited due to the significant increase in both patient and physician radiation exposure [34].

More recently with the introduction of compatible instrumentation, MRI has been employed for percutaneous cryoablation. The advantages of MRI include excellent anatomic resolution with the ability for multiplanar imaging; excellent monitoring of the ice ball, including its extension into perinephric fat; ability to visualize renal tumors without the need for contrast agents; and perhaps most importantly, the lack of ionizing radiation. The procedures are generally performed in open-gantry MRI scanners so there is no issue in patients with claustrophobia. The primary disadvantage is that most institutions do not have the capacity to have an MRI dedicated to interventional procedures. Also, many anesthesia monitoring devices such as electrocardiography (ECG) leads/wires are not MRI compatible.

We perform the vast majority of percutaneous cryoablation using CT imaging guidance. Although patients can be placed in multiple positions, we prefer to use the prone position as it is generally comfortable for the patient and, for most tumors, allows for the shortest distance from the skin to the kidney. For patients in whom prone positioning is not possible due to comorbidity, a lateral decubitus position can be employed. This position may also be advantageous for anterior renal tumors as the bowel displaces medially away from the kidney. Following positioning, an initial scan of the abdomen is performed with a radio-opaque grid on the skin over the ipsilateral kidney (Figure 112.1). Based on the location of the tumor and the corresponding marker on the skin grid, a localization needle is inserted to mimic the angle of probe insertion. The angle of insertion into the tumor does not appear to affect the efficacy of ablation [35]. However, the angle of the probe should be directed away from the collecting system for tumors abutting the collecting system (Figure 112.2). Animal studies have suggested that freezing into the collecting system is associated with significantly increased risk of urine leak if there is a concomitant puncture of the calyx [36]. Once the needle is in place, the distance from the center of the tumor to the skin is measured. A biopsy needle or cryoprobe is inserted percutaneously and advanced on the same trajectory half the distance to the tumor. A repeat scan is performed confirming the proper angle of the probe. The probe is then advanced into the tumor. Once the initial probe is in place, additional

(B) Localization needle placed into the subcutaneous space positioned at an angle directed at the mass. (C) Using the localization needle as a guide, the initial probe is inserted into the inferior aspect of the tumor. (D) Once all probes are in position, the freeze–thaw cycle is initiated and the ice ball is monitored.

probes, depending on the size of the tumor, can be inserted in parallel to mold an appropriate ablation zone.

Cryoprobes

During the early history of modern cryosurgery for renal tumors, the smallest liquid nitrogen-based cryoprobes were 3 mm in diameter. The development of vacuum-insulated argon gas-based systems using the Joule–Thompson effect resulted in significantly smaller diameter probes. Today, the two primary manufacturers of argon-based cryotherapy systems, Galil Medical Inc (Arden Hills, MI, USA) and HealthTronics Inc (formerly Endocare Inc; Austin, TX, USA), offer probes as small as 17G (1.74 mm). Probes are constructed in different

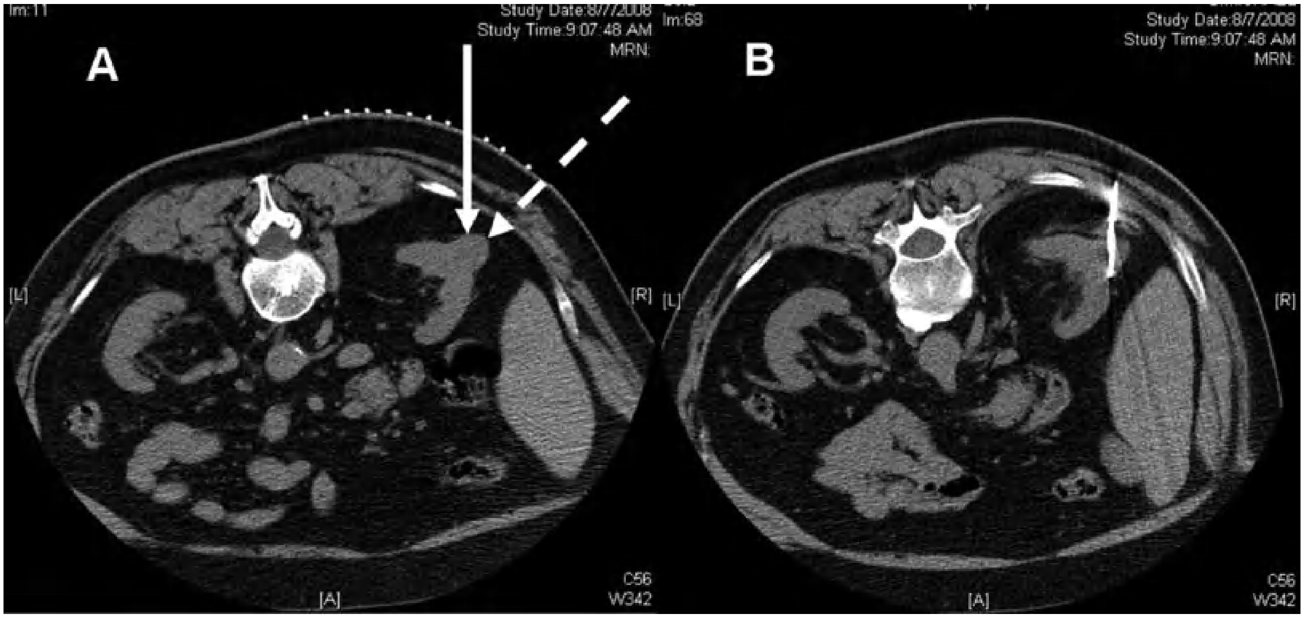

Figure 112.2 Angle of probe insertion should be directed away from the collecting system. (A) CT scan abdomen showing a right renal mass. The dashed arrow shows the improper angle of probe insertion while the solid arrow shows a better angle of approach to avoid puncture into the collecting system. (B) Final probe placement into the renal lesion.

lengths to accommodate different tumor access lengths. Due to the size of the probe handles, close parallel probe placement can sometimes be difficult. In these cases, the use of multiple length probes can circumvent the difficulty of several probes in close proximity. Probes are also designed to produce ice balls of different sizes and a variety of configurations, i.e. spherical versus oblong [37]. Therefore, depending on the size and location of the renal tumor, the urologist and interventional radiologist can plan the number of probes needed and the size/configuration with the goal of sculpting the ice ball to safely encompass the tumor and a margin of normal renal parenchyma.

Monitoring of the ice ball

Critical to successful percutaneous ablation of renal tumors is the monitoring of the ice ball to ensure an adequate and safe zone of ablation. During laparoscopic cryoablation, ultrasonography on the contralateral surface of the kidney can reliably visualize the hyperechoic leading edge as the ice ball expands [38]. However, ultrasound guidance during percutaneous ablation is more limited. On the other hand, CT and MRI provide excellent imaging of the expanding ice ball (Figure 112.3). Our practice is to scan the patient at 4 min and 9 min of each 10-min freeze cycle to ensure that the zone of ablation extends at least 5 mm beyond the edge of the tumor. Published isotherms indicate that lethal temperatures lower than –20°C are found 3–5 mm inside the edge of the advancing ice ball. Of course, this is predicated on the fact that the manufacturer-established isotherms, which were developed in nonhuman, nonliving, nonsolid sources, are accurate [39]. Young *et al*. sought to independently measure isotherms in both an *ex vivo* and *in vivo* model [40]. Their results were somewhat surprising in that temperatures 5 mm distal to the tip of the probe *in vivo* were as high as 19–27°C. The authors concluded that the tip of the probe should be advanced 5 mm beyond the edge of the tumor to ensure adequate lethal cooling temperatures. In addition, isotherms may be altered when treating tumors located adjacent to large vessels secondary to a heat sink effect, which results in warmer than expected temperatures. This effect is caused by convection heat transfer from circulating 37°C blood in the neighboring vessel. Given the uncertainty of isotherms, some urologists advocate the routine use of intraparenchymal thermal sensors to monitor the temperature adjacent to the tumor during ablation.

Maneuvers to limit collateral damage

The most dreaded and difficult complication of percutaneous cryoablation is injury to adjacent structures, such as the ureter, major renal vessels, paraspinal muscles, and the bowel. There are several techniques that can be used to increase the safe distance between the tumor and critical structures and therefore, to reduce the risk of iatrogenic injury. The most commonly used

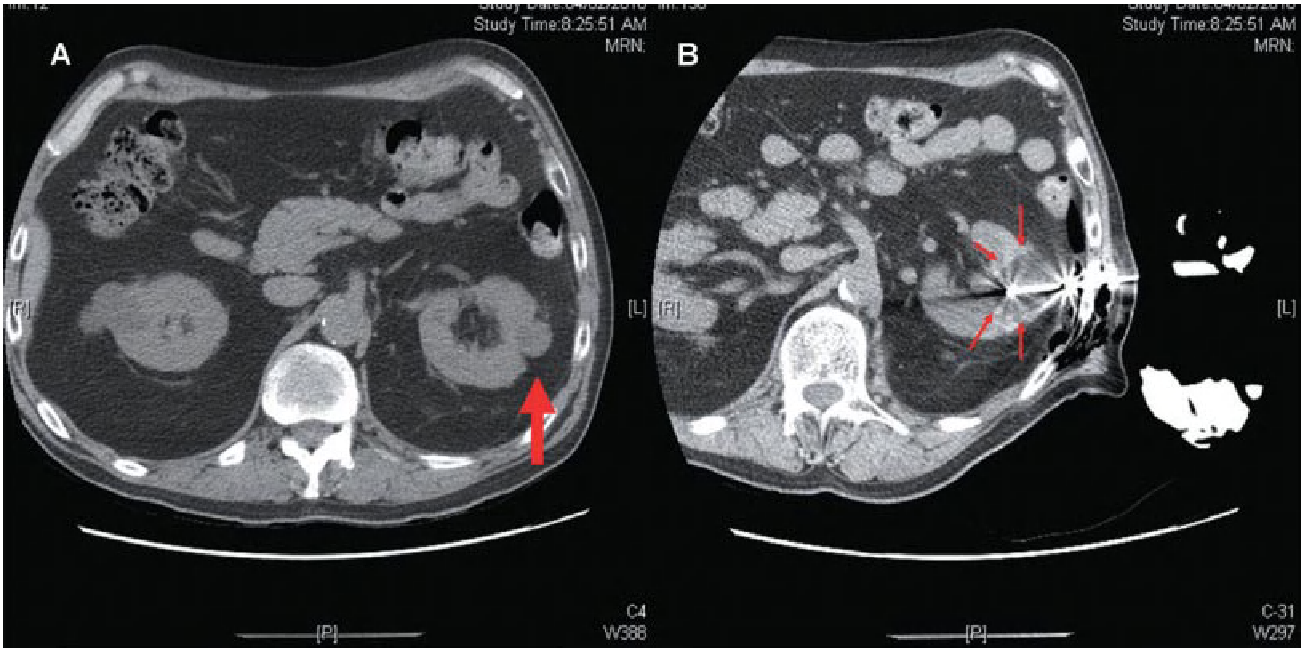

Figure 112.3 Monitoring of the ice ball using CT guidance. (A) Noncontrast CT of the abdomen shows a 2.3-cm mass in the lateral aspect of the left kidney (arrow). (B) Following cryoprobe insertion, CT image at 9 min of freezing shows the expanding ice ball as a region of decreased attenuation (marked by arrows).

technique is hydrodissection. A hollow bore needle is placed into the perinephric space between the kidney and the critical structure. Sterile water is then injected into the space, resulting in displacement of the organ (Figure 112.4). Arellano *et al*. retrospectively reviewed 36 ablation procedures in which hydrodissection was used and reported an increase in distance from an average of 0.36 cm to 1.94 cm [41]. Air can also be injected into the space and will track around the kidney, preferentially filling posterior spaces (for patients in the prone position). Ginat *et al*. retrospectively evaluated 11 percutaneous ablation cases in which displacement of the bowel was necessary [42]. In eight cases hydrodissection alone was successful (mean 105 mL injected), one case required hydrodissection with external torque on the ablation probe, and in two cases hydrodissection was completely unsuccessful. Overall, they reported a mean displacement of 1.7 cm, including the two failed cases; in the latter two cases, a 4-cm angioplasty air-filled balloon was placed between the bowel and tumor. Some centers have utilized diluted iodinated contrast for hydrodissection to better visualize the interceding fluid [43].

Lower pole medial tumors are often in close proximity to the ureter. Another method besides hydrodissection to protect the ureter is cystoscopic placement of a ureteral catheter. The catheter is then connected to a warm fluid source with slow irrigation. The warm infusion protects the ureter from thermal damage [this technique can be used for radiofrequency ablation (RFA) with cold fluid irrigation]. Ureteral catheters with cold water infusion were inserted by Cantwell *et al*. in 17 patients undergoing RFA within 1.5 cm of the ureter; at a mean follow-up of 14 months, they reported no strictures or hydronephrosis [44]. Another method of displacement away from the ureter is by external probe retraction. Following probe placement into the tumor, a "stick" freeze is performed (temperature at –10° C), resulting in a small ice ball at the tip of the probe. Externally, the probe is retracted either manually or by placing a bolster (such as a rolled towel) between the patient's skin and the probe handle. This maneuver can increase the distance as much as 10–12 mm, as demonstrated by a recent report in three cases [45]. We have used this technique to rotate tumors away from the renal artery as well (Figure 112.5).

Probe removal and hemostasis

Once the double freeze–thaw cycle ablation is completed, the probes are carefully removed to avoid renal fracture and postprocedure hematoma. We recommend that probes are not removed until the temperature reaches 25–28° C to ensure that no residual ice ball remains. In order to reduce the risk of postprobe removal hemorrhage, some investigators have advocated the injection of coagulants or tissue sealants [46]. However, this requires the use of a coaxial system or sheath during probe placement.

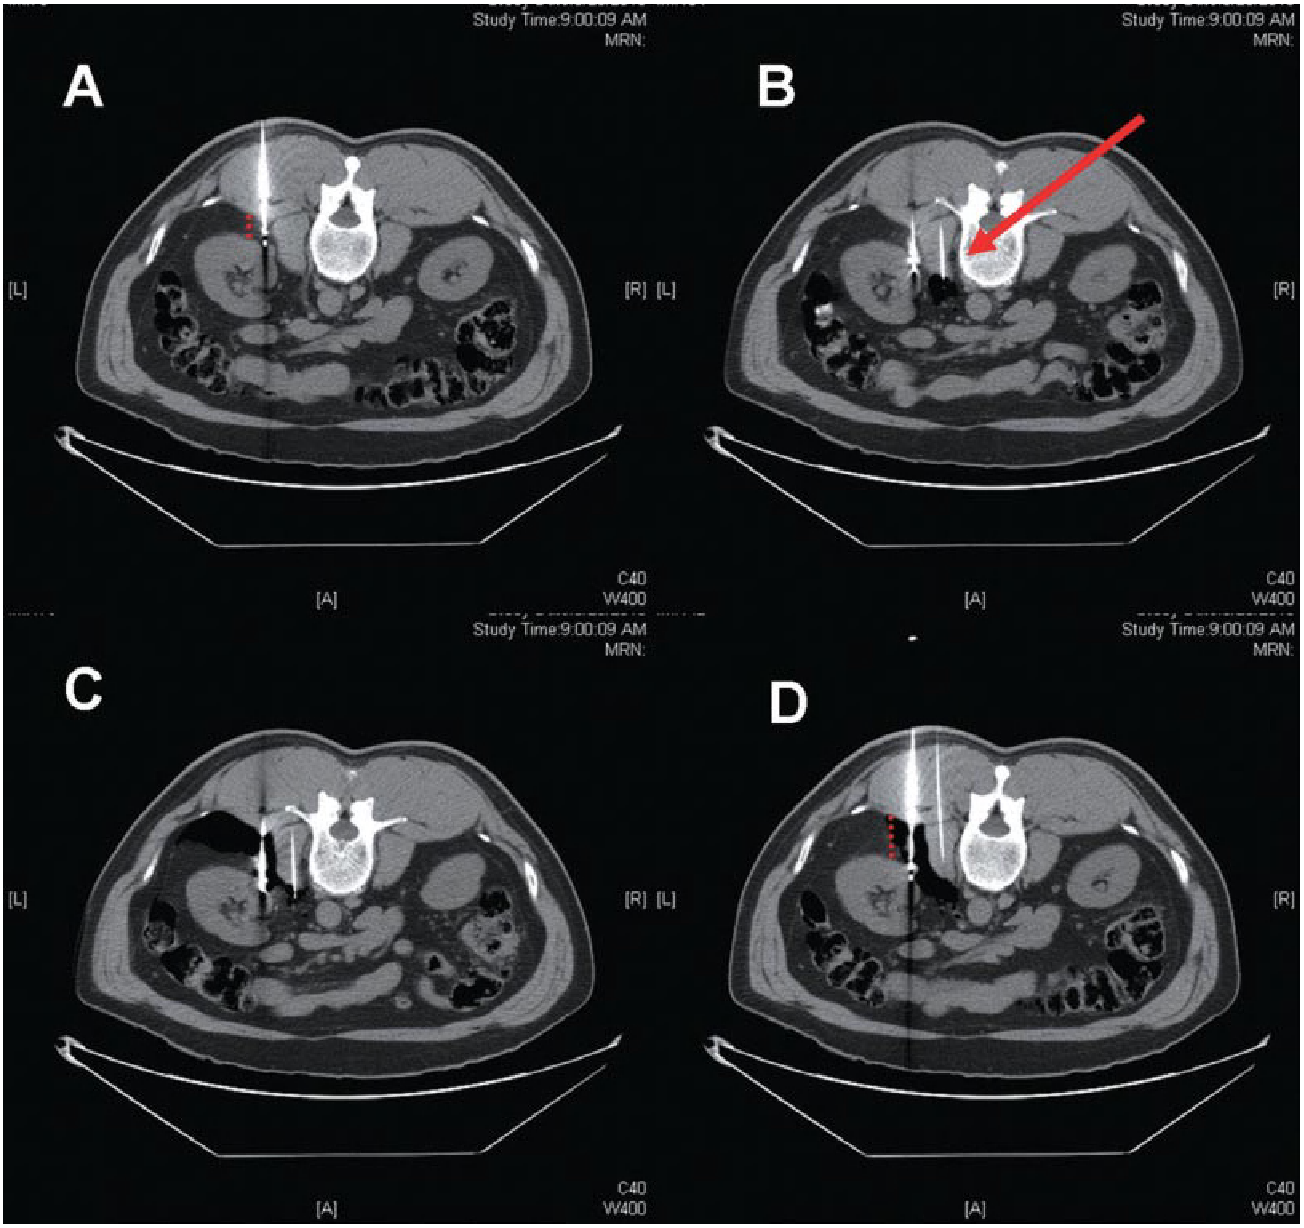

Figure 112.4 Pneumodissection to displace neighboring organs. (A) Probe placement into small posterior left renal lesion abutting the psoas muscle (dotted line). (B) An 18G spinal needle is advanced into the retroperitoneal space and air is injected (arrow). (C) Pneumodissection moves the kidney off the psoas muscle. (D) At the beginning of the freeze–thaw cycle, the distance between the kidney and psoas muscle has increased (dotted line) to reduce the chance of significant thermal injury to muscle.

Oncologic and functional outcomes

Percutaneous renal cryoablation was first reported in 1995 by Uchida *et al.* in two patients with metastatic renal cell carcinoma (RCC) [4]. An 8.4-mm probe was inserted into the center of the tumor and cooled to –20°C. Subsequent scans revealed a 68% and 20% reduction in the tumor size and remarkably, both patients experienced temporary significant improvement in functional status. Following this report, investigators studied renal cryoablation as a curative treatment for small renal masses. Initially, a laparoscopy-assisted technique, in which the kidney was mobilized and the tumor isolated, was employed. The probe was inserted under direct vision and laparoscopic ultrasound was used to monitor the ice ball. Several single-institution series of laparoscopic cryoablation have since demonstrated excellent long-term oncologic efficacy [47, 48].

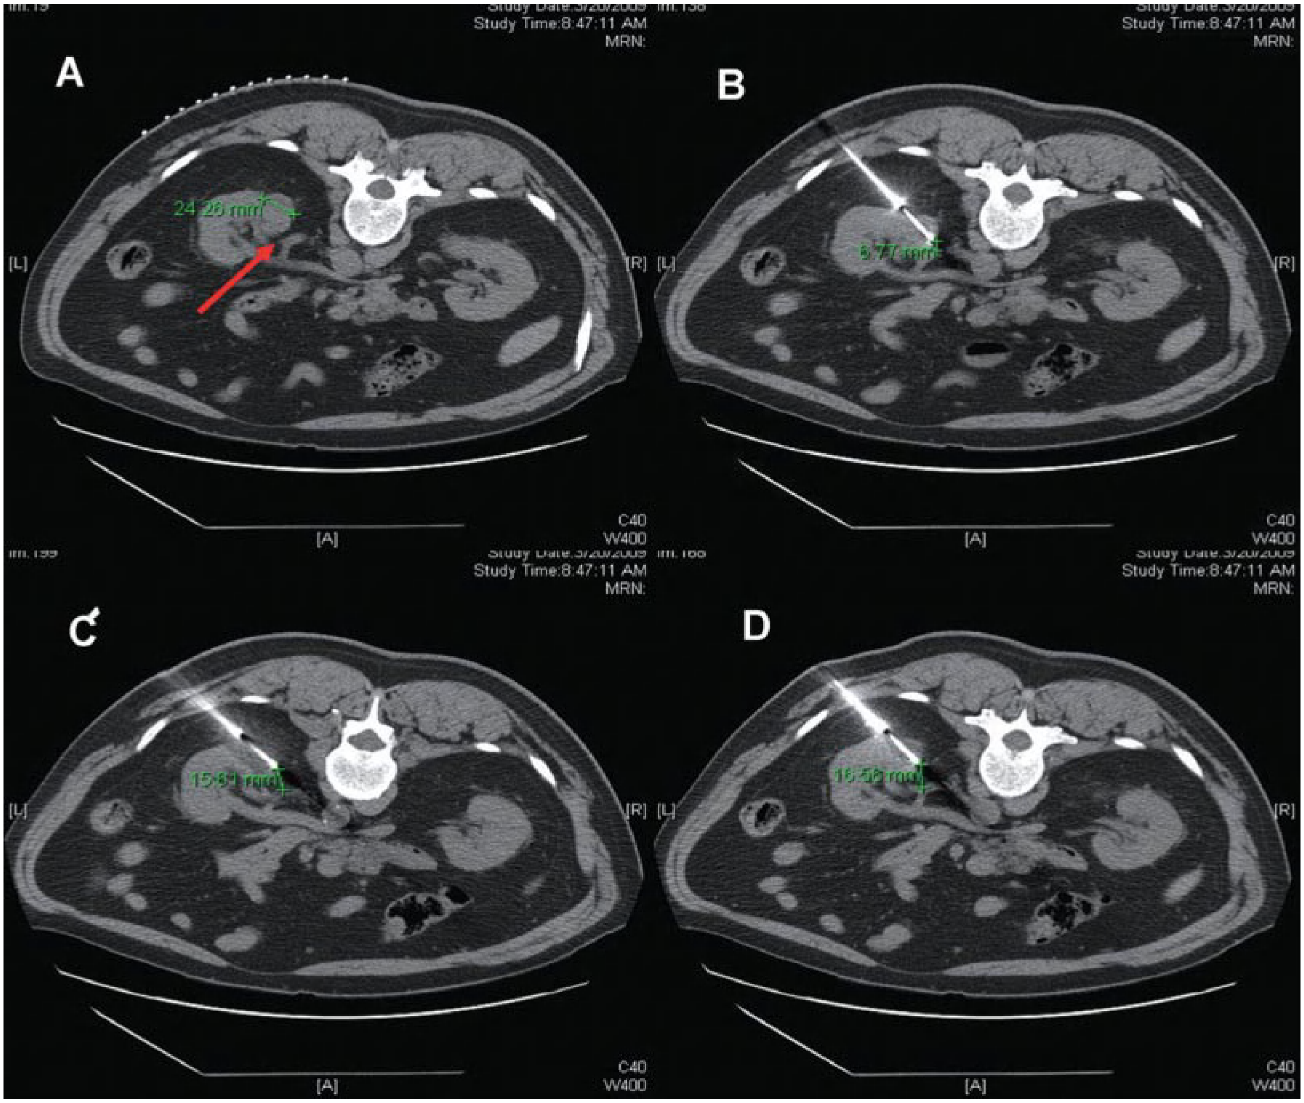

Figure 112.5 External manual displacement. (A) Noncontrast CT abdomen shows a 2.4-cm left posterior medial mass in close proximity to the renal vasculature (space marked by arrow). (B) Following cryoprobe placement into the tumor, the distance between the edge of the probe and renal vessel is 6.7 mm. (C, D) With the probe in "stick" mode (–10°C), external manual displacement with a rolled towel increases the distance between probe and renal vessel to 16.5 mm. Cryoablation is safely performed without injury to vasculature.

Given the success of laparoscopic ablation, percutaneous renal cryoablation has become more accepted and is now being used to treat more complex tumors.

Table 112.1 lists the largest percutaneous renal cryoablation series reported in the literature to date. Although intermediate and long-term follow-up is still necessary, early results show excellent oncologic efficacy. Overall, approximately 80% of the treated lesions in the reported studies were biopsy-proven RCC with an average size of 2.8 cm. Local recurrence or treatment failure rates have been reported to be between 2.5% and 25% at a mean follow-up of 7–30 months. For patients with solitary kidneys, Weisbrod *et al*. reported similar excellent short-term oncologic results with initial technical success in 32 of 35 patients (92%) and no evidence of recurrence in the 32 successfully treated patients at a mean follow-up of 14 months [49]. Percutaneous cryoablation has been successful even for larger tumors. Schmit *et al*. reported results in 108 patients with 110 tumors greater than 3 cm in size [50]. Overall, 107 of the 110 tumors were completely treated with a single ablation, as demonstrated by a lack of contrast enhancement at the 3-month CT scan. Follow-up was available in 82 patients, and at a mean follow-up of 14 months no patient demonstrated local tumor recurrence (as evidenced by residual contrast enhancement on CT or MRI).

NR, not reported.

One of the most controversial topics in renal tumor cryoablation is defining local recurrence or treatment failure. Currently, the standard of care is to follow patients with contrast-enhanced cross-sectional imaging. Any residual enhancement is considered suspicious for undertreatment or recurrence. Most reports describe either focal nodular enhancement or a crescent-shaped enhancement at the border of the ablation zone. This was confirmed in a study by Weight *et al*. in which post-treatment biopsy following cryoablation was found to highly correlate with post-treatment imaging findings [51]. The timing of imaging is also debated. Our practice is to perform the first imaging 4–6 months after treatment. Earlier imaging may show residual enhancement but may not be indicative of treatment failure. Porter *et al*. reported that a high proportion of studies showing enhancement within 3 months of cryoablation resolved by 6-months [52]. Typically, in contrast to RFA lesions, tumors treated by cryoablation undergo involution over time with a decrease in the size of the treated area. The current recommendations from the Society of Interventional Radiology are for consideration of early imaging (1 week to 1 month) to confirm complete treatment (i.e. the ablation encompasses the entire tumor) and subsequent imaging by either CT or MRI at regular intervals to confirm treatment efficacy [33].

The management of local failures or recurrences is another debated topic. Breda *et al*. performed a review of the literature and found that 60–75% of local failures are treated with repeat ablations with good success [53]. There are also frequent reports in the literature of patients with post-treatment enhancement on imaging who are followed conservatively; however, there are no long-term studies to determine whether these patients are at risk for distant failure. Finally, salvage extirpative surgery is always an option. Our experience has been that postablation surgery is difficult due to extensive scarring and desmoplastic reaction around the treatment site. Nephron-sparing salvage surgery can be performed in selected cases, but many patients will require nephrectomy.

Functional outcomes

Overall, the functional outcomes following percutaneous cryoablation are excellent. Most series report an

average hospital stay of 0–1 days with relatively quick return to baseline activity level. Two single-institution retrospective studies comparing laparoscopic cryoablation to percutaneous cryoablation reported significantly lower length of stay, decreased narcotic use, and faster return to activity [54, 55]. Furthermore, Hinshaw *et al*. reported 40% lower hospital charges for patients undergoing percutaneous versus laparoscopic cryoablation [56]. With regards to renal functional outcome, no series in the literature has reported significant changes in post-treatment creatinine. Specifically, in two different reports of cryoablation in solitary kidneys, neither study found a clinically significant change in post-treatment serum creatinine [49, 57].

Complications

Table 112.1 also shows the major complication rates as reported in these series of patients, with a range of 0–6%. Minor complications can occur in up to 25% of patients with most not requiring specific treatment other than observation. The two most common complications are flank pain and clinically significant hematoma. Flank pain can result from thermal injury to the paraspinal and psoas muscles during treatment. The pain is generally self-limited and managed with narcotic pain medications. More prolonged and significant pain can occur with thermal damage to the genitofemoral nerve or intercostal nerves innervating the abdomen. Fluid hydrodissection is helpful to move the zone of ablation off the posterior abdominal wall to reduce this risk (see above).

Hematoma and hemorrhage is by far the most common nonpain-related complication. Most series report post-treatment transfusion rates of less than 5%. The risk of hematoma directly correlates with increasing size of the tumor and number of probes [58, 59]. Our experience has been that tumors larger than 3 cm have a significantly higher post-treatment hemorrhage risk as compared to smaller tumors. The rare patient with actively ongoing post-treatment hemorrhage most often does not require surgical exploration; in contrast, angiogram with coil embolization of the offending vessel is successful in virtually all cases.

Bowel injury from thermal injury to the bowel wall can be a devastating complication. Most cases present in a delayed manner with abscess and fistula formation. Although conservative management by percutaneous drainage has been reported, most patients will require laparotomy with or without bowel resection [60]. Ureteral injury is a relatively rare complication of cryoablation (more commonly reported with RFA) and manifests as a ureteral stricture and hydronephrosis on follow-up studies. These injuries can be prevented by pretreatment placement of a ureteral catheter with warm saline irrigations (see above). Although the strictures can be managed temporarily by stenting, long-term resolution is achieved only by surgical reconstruction.

Pneumothorax is another relatively common complication that can occur during access to upper pole tumors. Specific attention to the lung bases during treatment imaging can identify if a pneumothorax has occurred. Most can be managed conservatively with serial chest X-ray; a chest tube is required only for large (>25%) or symptomatic occurrences.

Finally, urine leak/fistula is a rare complication that results from puncture injury of the collecting system followed by thermal ablation involvement of the injured calyx. This scenario occurs during the treatment of large tumors or those abutting the collecting system. Avoidance of calyceal puncture during probe placement is the primary preventive measure as ablation into the collecting system alone has been shown to be safe. Management of an urinoma centers on percutaneous drainage. As long as there is no distal obstruction, most urine leaks will resolve spontaneously.

Future directions and conclusions

Percutaneous renal cryoablation of small renal masses has become an accepted treatment modality not only for patients who are not surgical candidates but also for those seeking treatments with less morbidity and shorter recovery. Future improvements will center on improved realtime imaging capabilities to shorten treatment times and potentially improve treatment efficacy by improving the accuracy of probe placement. Haber *et al*. reported on initial experience with realtime ultrasonography fused with three-dimensional CT imaging in a porcine model to improve precision of percutaneous probe placement [61]. Investigators have already made significant strides in the use of automated devices and robotics for percutaneous needle placement into the kidney [62, 63]. In addition, longer follow-up studies are needed to demonstrate long-term oncologic efficacy in order for percutaneous cryoablation to become an equal alternative to partial nephrectomy.

CHAPTER 113
Image-Guided Prostate Brachytherapy

Louis Potters & Lucille Lee
Department of Radiation Medicine, Hofstra North Shore–LIJ School of Medicine at Hofstra University, New Hyde Park, NY, USA

Introduction

In the era of routine prostate-specific antigen (PSA) screening, prostate cancer has become the most common cancer in men. In 2008, it was estimated that over 186 000 men would be diagnosed with prostate cancer, with only 10% of these men being diagnosed with high-risk prostate cancer [1, 2]. This shift toward low-risk disease, as well as younger age at the time of diagnosis, not only improves the potential outcomes of treatment, but also emphasizes the need to discuss treatment options within the context of quality-of-life outcomes. Long-term results have shown that oncologic control or "cure" is attainable with definitive treatment in a high percentage of cases. Currently surgical removal (prostatectomy) [3] and permanent prostate brachytherapy (PPB) [4] have demonstrated their ability to achieve similar and acceptable rates of control. Other treatment modalities, including external beam therapy using intensity-modulated radiation therapy (IMRT) [5], cryotherapy [6], and radiofrequency ablation (RFA) [7] also appear to be effective in select cases, although long-term data are lacking. This chapter reviews outcomes of PPB in the management of prostate cancer.

History of prostate brachytherapy

Prostate brachytherapy predates radical prostatectomy, having been introduced in the 1920s with radium needle implants. Later, in the 1960s, radioactive gold seeds were used to treat prostate cancer [8]. Outcomes were poorly reported in the pre-PSA era and the complexity of working with radioactive isotopes hampered its acceptance as a treatment modality. Interest in brachytherapy re-emerged in the 1970s when Whitmore and associates at Memorial Sloan Kettering in New York established an open, retropubic approach using iodine-125 seeds [9]. However, trying to uniformly implant the exposed gland did not prove to be the best way to achieve homogenous dose coverage. The 15-year outcomes were disappointing, with only 21% of patients reported to be controlled.

A resurgence of prostate brachytherapy occurred in the 1980s due to the transperineal approach developed by Holm *et al.* [10]. The approach adopted in Seattle utilized a "pre-plan" to account for the seed placement, while in New York a more conservative approach was developed to limit the morbidity of the procedure by peripherally placing seeds to limit central hot spots [11]. Given the ability for realtime image guidance of implant *in situ*, excellent results have been obtained with PPB, and both approaches remain active to this day.

Patient selection

Implantation of the prostate is an attractive option because it concentrates treatment on the prostate and minimizes radiation exposure and morbidity to nearby organs, including the bladder, rectum, and small bowel. PPB is an outpatient procedure and the patient may resume 100% of physical activity within 24 h. The implant serves as the delivery mode of the isotopes, which decay over time and represent the actual treatment.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Because PPB utilizes realtime ultrasound-based image guidance, this procedure is truly conformal and allows for high radiation doses to be delivered to the prostate. While the urethra remains central within the prostate and cannot be excluded from radiation exposure, newer approaches of PPB allow urethral sparing [12].

The ideal candidate for PPB is one with clinically confined disease, as is the case for patients considering radical prostatectomy. Risk stratification of disease by initial PSA value and Gleason score better predicts outcome and allows for treatment modification to account for those men with high-risk disease. Where the risk of extraprostatic disease is high, there is the need to combine PPB with external beam radiotherapy (EBRT).

PPB is associated with urinary bother that may be mild, or protracted and quite bothersome to the patient. Indwelling catheterization has been reported in 2–20% of patients following PPB. Higher rates of acute urinary obstruction date back to older techniques that failed to spare high doses centrally within the prostate. Other factors associated with increased postimplant urinary bother include a high initial International Prostate Symptom Score (IPSS) score (>7–10) and an enlarged prostate volume [13]. Patients with either or both of these factors need to be coached carefully before undergoing PPB. While it is customary to offer men with enlarged prostates a 3-month course of androgen ablation to reduce the prostate volume, there are data from Crook *et al*. suggesting that this does not reduce postimplant urinary bother [14]. Further, the long-term impact on potency of even a 3-month course of androgen ablative therapy needs to be considered. Patients with enlarged prostates and high IPSS scores may wish to consider EBRT as definitive treatment.

At present, an age-related bias exists within the urologic community, with younger patients being referred more often for radical prostatectomy than either radiation or no therapy. In a recent study from Shaprio *et al.*, men younger than 60 years of age had identical biochemical outcomes at 5 and 10 years when compared to patients over 60 years of age, suggesting that age should not bias PPB as an option in younger men [15]. However, the risk of second primary cancers (SPCs) is an important consideration when offering PPB.

It is well known that radiation exposure is associated with SPCs. Several studies have shown an increased risk of bladder and colorectal cancer in men who were treated with radiation for prostate cancer [16, 17]. However, these studies were in patients treated with EBRT using older, conventional techniques. Brachytherapy, which is a highly conformal therapy, appears to have a lower SPC risk than EBRT [18, 19]. Nevertheless, this remains a valid concern and should be discussed with each patient.

Technical issues

PPB is currently performed as per Holm [10] via a transperitoneal approach with realtime ultrasound visualization of the prostate. Accurate placement of the needles is achieved with this technique and the isotopes are placed through them into the prostate. Outcomes following PPB clearly identify that implant quality relative to the delivered dose is key to a successful outcome. Several approaches are used for seed implant, but the key to success is more the implant quality than the technique.

One approach calls for linked or stranded seeds to be placed based on a “pre-plan” of the implant. One advantage of this technique is that the seeds cannot migrate from the prostate.

Another approach is a realtime, adaptive implant, using an interstitial gun to place each seed. Using intraoperative software, a “forward” plan can be generated based on the exact prostate volume and location. With the dynamic–adaptive implant approach, there is less of a learning curve for physicians and centers starting PPB programs [20]. Also, with dynamic and adaptive assessment, fewer sources can be used while maintaining a high quality implant. Use of fewer seeds offers an opportunity for reducing both the rectal and urethral doses while still achieving adequate prostate coverage. Outcomes have identified less urinary bother with this approach.

^{125}I was the isotope used at the time of the Whitmore implants and it continues to be used for PPB. In the early 1990s, palladium-103 was introduced. Given its shorter half-life, it was postulated that ^{103}Pd would become the preferred isotope for tumors of higher Gleason score, because of their faster tumor doubling time [21]. In 2003, cesium-131 was introduced as a third isotope for PPB. ^{131}Cs has even a shorter half-life than ^{103}Pd, which has the advantage of a shorter period to follow radiation exposure precautions following the implant. Nevertheless, there have been no data to date to suggest that isotope choice should be based on tumor grade or prostate cancer doubling time. In a recent abstract of retrospective data, Cho *et al*. reported an advantage for ^{103}Pd over ^{125}I [22].

Results

Studies reporting long-term outcomes following PPB are now mature, longer than 10 years in many men, but without randomized data it is difficult to compare PPB to EBRT or radical prostatectomy. However, using PSA surrogates to define a successful outcome, it appears that PPB is at least equivalent to radical prostatectomy and perhaps slightly better than EBRT.

To delineate outcomes in men treated with radiation, a recent study from the University of California at San Francisco (UCSF) compared endorectal magnetic resonance spectroscopy imaging (eMRSI) responses between PPB and EBRT. For each parameter assessed, PPB outperformed EBRT in the median time both to spectroscopic evidence of disease ablation (24.8 and 32.2 months, respectively) and to nadir PSA (38.0 and 52.4 months, respectively) [23].

Long-term data in excess of 10 years support the use of PPB in the definitive treatment of low-risk prostate cancer. Potters *et al*. have reported a 12-year biochemical control rate (bNED) of 81% in a cohort of 1449 patients [4]. Freedom from biochemical recurrence for low-risk patients was 91%. Similarly, Grimm *et al*. showed that the PSA progression-free survival at 10 years was 87% for low-risk patients [24]. While younger patients look for longer-term outcomes, it must be remembered that for PPB, radical prostatectomy, and EBRT, outcomes that exceed 10–15 years are pushing against the early experience of PSA screening. Stage and grade migration over time may make long-term data less relevant to the current patient.

Outcomes for men with low-risk disease are excellent, with bNED rates greater than 90% at 8–12 years [4]. In several studies, implant quality as measured by the D90 dose (the radiation dose that covers 90% of the prostate volume) correlates with outcome. Therefore, the importance of implant quality needs to be emphasized.

For patients with intermediate-risk prostate cancer, Blasko *et al*. identified that the addition of EBRT to PPB was no better than PPB as monotherapy [25]; 5-year biochemical success rates were 85% versus 84%, respectively. Potters *et al*. also failed to identify an advantage of adding EBRT on Cox regression analysis of intermediate-risk patients [4]. One hypothesis is that poor implant quality, as measured by the D90 dose, can be compensated for by the addition of EBRT. With new techniques, such as dynamic–adaptive PPB, the D90 dose can be controlled intraoperatively, and further negates the need for combined therapy, especially in low- and intermediate-risk patients.

A predictive model for a postimplant nomogram for prostate cancer recurrence at 9 years has recently been reported from a large multi-institutional analysis of 5889 PPB patients [26]. This study further confirmed the significance of implant dosimetry for predicting outcome. Unique to predictive models, this nomogram may be used *a priori* to calculate a D90 dose that likely achieves a desired outcome with further validation. Thus, a personalized dose prescription can be calculated for each patient.

Although the treatment of high-risk prostate cancer is beyond the scope of this review, there appears to be both a dose and radiation field effect associated with PPB. In a multicenter analysis of 3928 patients, Stone *et al*. found that patients with high-risk prostate cancer benefited the most from an escalation in the biologic equivalent dose (BED) compared to the dose typically prescribed to patients with low-risk prostate cancer [27]. Additionally, a radiation field effect was suggested in a phase III trial (RTOG 9413), which demonstrated whole pelvic radiation with a cone-down or boost to the prostate was superior to local field radiation [28].

Many of the side effects seen with brachytherapy are associated with radiation exposure of the urethra, bladder, and rectum. These side effects can have serious quality-of-life implications, and brachytherapy requires informed consent from the patient.

In a prospective analysis of the quality of life of patients undergoing primary treatment for prostate cancer, Sanda *et al*. found that patients undergoing brachytherapy had a significant detriment in urinary irritation or obstruction scores compared to baseline [29]. As noted, factors associated with a greater detriment in urinary irritation or obstruction included a large prostate size and a high IPSS score. In the Sanda *et al.* study, these factors were not controlled for, suggesting that patient selection remains important. Similar to patients treated with EBRT and radical prostatectomy, PPB patients were found to have detriments in the domains of sexual function, urinary incontinence, bowel or rectal function, and vitality when compared to baseline. Changes in these domains were found to have a subsequent impact on the patient's satisfaction with the overall outcome of the treatment. Yet, for the sexual domain, PPB patients performed better than those treated with EBRT and radical prostatectomy [29].

Given the impact of erectile dysfunction on quality of life in an ever-younger cohort of newly diagnosed prostate cancer patients, it is vital to discuss the impact of sexual function with each patient. In a recent retrospective analysis Seideman *et al.* demonstrated a potency preservation rate of 66.4% at 9 years among males under the age of 60 undergoing PPB [30].

Comparative effectiveness and value

Recently, the Institute for Clinical and Economic Review (ICER) published their analysis of prostate brachytherapy versus IMRT EBRT or proton beam therapy (PBT) [31]. This analysis examined a total of 166 studies and found large differences in lifetime cost, with brachytherapy having 30% and 60% lower costs than IMRT EBRT and PBT, respectively [brachytherapy US$29 575 with 13.90 quality-adjusted life years (QALYs); IMRT EBRT US$41 591 at 13.81 QALYs; PBT $72 789 at 13.70 QALYs).

The evidence-based rating matrix assessment used by the ICER combines a rating for comparative clinical

effectiveness and a rating for comparative value. Its comparing IMRT and brachytherapy identified a comparable clinical effectiveness of brachytherapy versus IMRT and an enhanced comparative value of brachytherapy versus IMRT. The results from this decision–analytic model suggest that brachytherapy is likely to be less expensive and result in slightly improved quality of life for a general population of patients compared to IMRT or PBT [31].

Conclusions

PPB is an established and cost-effective treatment for localized prostate cancer. Although randomized studies comparing PPB to other treatment modalities such as EBRT and prostatectomy are lacking, acceptable long-term outcomes in thousands of brachytherapy patients have been described. Given the overall prognosis of men with prostate cancer, coupled with the efficiency and durability of PPB, it is hard to make an argument for patients being treated by experimental radiation modalities outside of a protocol. While PPB needs to be selected carefully, based on IPSS score and prostate size, as well as other comorbidities, it remains a mainstay in the arsenal for prostate cancer. Given its cost–benefit advantage over more expensive radiation therapy modalities, brachytherapy should be the primary modality for men requiring radiation treatment for prostate cancer.

CHAPTER 114
Image-Guided External Beam Radiotherapy

Lucille Lee & Louis Potters
Department of Radiation Medicine, North Shore – Long Island Jewish Health System, New Hyde Park, NY, USA

Introduction

External beam radiotherapy (EBRT) is a targeted treatment that relies on imaging to provide surrogates for areas of interest, such as tumors, in order to focus the radiation beam. The quality of treatment depends on the imaging used to plan and deliver the treatment. As a result, improvements in the delivery of radiation therapy have been primarily based on advances in imaging modalities and the ability to incorporate these into the planning and delivery of treatment. Recent examples include computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). In addition, computer technology has made it easier to incorporate an increasing number of customized beams, which allow the radiation dose to be further concentrated in the area of interest. The advent of these high-quality imaging techniques coupled with the use of computerized treatment delivery have enhanced the accuracy of delivering radiation dose to a target to within millimeters and are the hallmarks of intensity-modulated radiation therapy (IMRT).

Traditional radiation treatments generally use wide margins to accommodate potential movement or uncertainties during a treatment course. Doses are often limited due to the exposure of radiosensitive nearby structures. With more precise treatments, the dose to a target structure can be increased while reducing the dose to a neighboring critical structure. Certain areas, such as the brain, are particularly amenable to these types of treatments because movement is minimal or can be easily controlled. Many other parts of the body are prone to movement with loss of sub-centimeter accuracy with, for example, casual breathing. In addition, tumors can change, either shrinking or actually growing during the treatment course. These movements and changes result in reduced accuracy and either underdosing the target or overdosing nearby critical structures. Treatments can be replanned multiple times during a treatment course for a target that changes in size; this is referred to as image adaptive radiation therapy (IART). However, this process is currently in the early stages and can be labor intensive. For targets that maintain the same size but are more prone to movement, various methods may be used to compensate for that movement; these are known as image-guided radiation therapy (IGRT). IGRT is particularly useful for treatment of prostate cancer, where the target size is relatively stable but is prone to movement. These techniques allow for dose escalation, which has been shown to improve the outcome of localized prostate cancer. Despite higher doses, the increased accuracy allows for tighter margins to be used, resulting in low morbidity. This chapter details the use of IGRT for the treatment of prostate cancer.

Prostate cancer

Epidemiology

Prostate cancer has become the most common cancer in males based on Surveillance, Epidemiology, and End Results (SEER) data. In 2010, 217 730 cases were expected in the USA. Between 1999 and 2005, 92% of cases were

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

diagnosed in the locoregional stages, for which the 5-year relative survival approaches 100%. An annual decrease of 42.4% between 2000 and 2006 reflects the decreased rates of detection and fewer undiagnosed cases resulting from the widespread use of prostate-specific antigen (PSA) screening in the 1980s and 1990s. Mortality has been declining since 1990, reflecting the use of screening PSA and improvements in treatment [1].

Screening

The American Urological Association (AUA) recently recommended two notable changes to prostate screening practice [2]. First, the age for obtaining a baseline PSA was lowered from 50 to 40 years, the rationale being that PSA screening is more specific for younger men and a better predictor for future development of prostate cancer than either family history or race. Second, the decision to obtain a prostate biopsy should not be based solely on a PSA above the threshold value but should be multifactorial, including digital rectal examination, free and total PSA, PSA velocity, PSA density, patient age, family history, ethnicity, prior biopsy history, and comorbidities [2]. Recently, published randomized trials comparing the mortality outcomes of a screened group versus a nonscreened group showed conflicting results [3, 4]. However, both studies suggested a high rate of overdetection and overtreatment. Therefore, the recommendation emphasizes an informed discussion of the risks and benefits of prostate cancer screening prior to biopsy, and the option of active surveillance instead of treatment for certain patients with prostate cancer.

Risk stratification

Once the diagnosis of prostate cancer is made, a staging work-up ensues in order to provide additional prognostic information for risk stratification, which may assist in management decisions. The National Comprehensive Cancer Network (NCCN) Version 1.2010 provides recurrence risk stratification among patients with clinically localized disease based on PSA level, Gleason score, clinical stage, and biopsy specifics (Table 114.1). The American Joint Committee on Cancer (AJCC) has recently incorporated PSA and Gleason score into a stage/prognostic group system (Table 114.2), while the TNM system for clinical and pathologic staging remains the same [5]. A CT scan may be obtained to assess clinically apparent adenopathy, but is generally not required for a PSA less than 25 ng/mL because the yield is too low to warrant its routine use [6]. Similarly, a bone scan may be obtained to determine the presence of bone metastases, but it is not generally required for a PSA less than 20 ng/mL [7]. Surgical lymph node staging is also considered unnecessary for the low-risk patient because the yield is low [6], and it is probably not necessary for the high-risk patient either because of the increasing use of pelvic nodal irradiation.

External beam radiation therapy for prostate cancer

Patient selection

Patients with disease localized to the prostate without evidence of lymph node or distant metastasis may be candidates for EBRT. There are relatively few general contraindications to the use of radiation therapy for treatment of definitive disease. These include prior treatment with pelvic radiation therapy and presence of active autoimmune disease, particularly scleroderma and lupus. Inflammatory bowel disease may be considered a relative contraindication for patients undergoing pelvic node irradiation, since treatment may be poorly tolerated [8, 9], but it is considered safe for patients undergoing treatment to the prostate alone [10]. AJCC Group 1 patients may be treated with EBRT alone or a brachytherapy implant (see Chapter 113) with the possible rare exception of patients with an unknown PSA or Gleason score. Patients with Group 2–3 disease are usually candidates for EBRT or the combined approach of a brachytherapy implant and reduced-dose EBRT.

Table 114.2 Prostate cancer anatomic stage/prognostic group according to the American Joint Committee on Cancer Prostate Cancer.

Group	T	N	M	PSA	Gleason
I	T1a–c	N0	M0	PSA < 10	Gleason ≤ 6
	T2a	N0	M0	PSA < 10	Gleason ≤ 6
	T1–2a	N0	M0	PSA X	Gleason X
IIA	T1a–c	N0	M0	PSA < 20	Gleason 7
	T1a–c	N0	M0	PSA ≥ 10–<20	Gleason ≤ 6
	T2a	N0	M0	PSA < 20	Gleason ≤ 7

III	T3a–b	N0	M0	PSA Any	Gleason Any
IV	T4	N0	M0	PSA Any	Gleason Any
	T Any	N1	M0	PSA Any	Gleason Any
	T Any	N Any	M1	PSA Any	Gleason Any

Selecting patients for brachytherapy

When deciding whether or not to use brachytherapy, either alone or in combination with EBRT, it is useful to consider pretreatment urologic symptoms and prostate size. Acute urologic symptoms may also be more severe with brachytherapy, which makes it less ideal for patients with significant symptoms of benign prostatic hypertrophy (BPH) and those with large glands, the general cut-off being 50 g. Urinary symptoms are commonly rated using the AUA International Prostate Symptom Score (Table 114.3) [11], which is the same at the BPH Symptom Score but with a quality-of-life (QOL) question added. In the phase III trial, RTOG 0815, patients with an AUA score of greater than 15 are not candidates for brachytherapy, and the size cut-off is less than 60 g. Also, patients with a history of transurethral resection of the prostate (TURP) should not receive brachytherapy because of the increased risk of urethral toxicity, including incontinence [9]. Other factors that contribute to higher acute toxicity include a greater number of needles used to do the implant and the use of hormonal therapy [12].

Combination external beam radiation therapy and brachytherapy

There are no data to support either using EBRT alone or combination EBRT and brachytherapy in the treatment of intermediate-to-high-risk prostate cancer. In theory, the higher incidence of extracapsular extension and seminal vesicle invasion in intermediate-to-high-risk patients is more adequately covered by EBRT than brachytherapy, which is the rationale for avoiding brachytherapy alone in these patients. On the other hand, certain intermediate-risk patients are likely to be candidates for brachytherapy alone. In a retrospective review of 668 brachytherapy patients, there was no statistically significant difference in the 8-year actuarial biochemical relapse-free survival (BRFS) between low- and intermediate-risk patients, 98.4% and 98.2%, respectively [13]. These data suggest that most intermediate-risk patients have a low risk of micrometastatic disease in the pelvis. Even though the risk of extracapsular disease is higher in these patients, these areas may be adequately covered by an implant, since most extracapsular disease is located within 5 mm of the prostate capsule. In another series of combination therapy, where 63.4% of the intermediate-risk patients had 50% or more positive biopsy needle cores, there was an 80% 15-year BRFS [14]. These data suggest excellent long-term control with the combined approach. However, despite high control rates, the additional use of EBRT may be detrimental in terms of higher rates of morbidity. Therefore, additional pathologic factors, such as number or percentage of positive cores, may be helpful to determine whether or not a combination treatment should be used.

Postprostatectomy external beam radiotherapy

Adjuvant or salvage EBRT is used in the postprostatectomy setting. In general, the indications for postprostatectomy adjuvant radiation therapy include: positive margins, seminal vesicle invasion, extracapsular extension, and detectable PSA. The European Association for Research and Treatment of Cancer (EORTC) 22911 prospective phase III trial randomizing postprostatectomy patients with capsular penetration, positive margins,

and/or seminal vesicle invasion to immediate radiation therapy of 60 Gy versus observation, showed an improvement in biochemical disease-free survival (BDFS) and disease progression, but no overall survival advantage. The 5-year progression-free survival was 74% for patients undergoing radiation therapy versus 52% undergoing observation [15]. The 5-year rate of grade 3 urinary toxicity was 2.6% in the observation arm and 4.2% in the treatment arm (P = ·0726). Similar findings were reported in a multi-institutional randomized clinical trial comparing adjuvant radiation therapy of 60–64 Gy to observation with a median follow-up of 10.5 years. The metastasis-free survival was 64.5% in the treated group versus 56.9% in the observation group (P = .06) [16]. So, although there was improvement in PSA relapse and disease recurrence, there was no significant difference in survival. Without an improvement in survival, the controversy regarding whether or not to use adjuvant radiation therapy continues.

Results

Definition of biochemical failure

Results are generally reported by risk group and using BRFS since significant overall survival data may require decades to obtain. The definition of biochemical failure has recently been revised. The American Society for Therapeutic Radiology and Oncology (ASTRO) definition for biochemical failure requires three consecutive rises in PSA above the nadir [17]. Because of problems including backdating and inaccuracies with brachytherapy, the Phoenix definition of PSA nadir plus 2 ng/mL has been adopted [18]. With either definition, the dependence of outcome on dose and risk group is clear.

Multi-institutional long-term results

A total of 4839 patients were studied between 1986 and 1995 in a multi-institutional report of EBRT alone for stage T1b, T1c or T2 disease using doses of at least 60 Gy and no androgen deprivation therapy (ADT). With a median follow-up of 6.8 years, the 5- and 8-year PSA-DFS was 58% and 53%, respectively. For doses of 70 Gy or more, the results were 61% and 55%, respectively [19]. Data were complied for the 1325 patients treated during 1994 and 1995, comparing doses above and below 72 Gy for low-, intermediate- and high-risk groups. The overall 5-year PSA-DFS estimates for under 72 Gy versus 72 Gy and over were 63% versus 69%, respectively (P = .046); for patients with low-risk tumors, 75% versus 79%, respectively (P = 0.359); for patients with intermediate-risk tumors, 63% versus 72%, respectively (P = 0.026); and for patients with high-risk tumors, 38% versus 46%, respectively (P = 0.126) [20].

Combination therapy

Long-term BRFS rates for 223 patients with clinical stages T1–T3 prostate cancer treated from 1987 to 1993 with ^{125}I or ^{103}Pd brachytherapy after 45-Gy neoadjuvant EBRT without ADT were reported using different risk models. The results for a subset of intermediate-risk patients were described above. Overall, the 15-year BRFS for the entire treatment group was 74%. By risk group, the 15-year BRFSs were: low risk 85.8%, intermediate risk 80.3%, and high risk 67.8% (P = .002) [14]. In this study, only two rises in PSA instead of three were used to define biochemical failure. Also, the traditional four-field box technique was used. This early standard wide-field technique is the basis for improvement (see Treatment planning below).

Whole pelvis radiation therapy for high-risk disease

Whole pelvis radiation therapy is used for high-risk disease to treat microscopic involvement of the pelvic lymph nodes. The dose to the pelvis ranges from 4500 to 5040 cGy in standard fractionation. A higher dose to the prostate can be given as an external beam cone-down or with brachytherapy. RTOG 94-13 is a four-arm study randomizing patients who are at greater than 15% risk of pelvic node metastasis to whole pelvis or prostate-only radiation therapy and neoadjuvant or adjuvant ADT. At last analysis, it was not clear that there is an advantage to whole pelvis radiation over prostate-only radiation [21]. Although a whole pelvic field has been standard for many trials treating high-risk prostate cancer, two of which are described below, further research will be needed to answer the question definitively. Since treatment to the whole pelvis increases the morbidity of treatment, the answer is of the utmost importance.

Androgen deprivation for high-risk disease

Neoadjuvant and concurrent ADT is generally recommended. RTOG 85-31 demonstrated a significant improvement in disease progression and absolute survival at 10 years with the addition of ADT to standard EBRT whole pelvis plus cone-down to total doses of between 65 and 70 Gy [22]. Between 1987 and 1992, 977 patients were randomized to goserelin with radiation therapy or at time of relapse. The 10-year survival rate was 49% in the treatment arm versus 39% in the delayed arm (P = .002). The 10-year local failure rate was 23% in the treatment arm versus 38% in the delayed arm (P < .0001). Similarly, a randomized phase III trial of the EORTC showed a significant DFS and overall survival

in favor of hormone therapy. Between the years 1987 and 1995, 415 patients were randomized to whole pelvis radiation therapy of 50 Gy plus a 20-Gy prostate cone-down with or without goserelin and cyproterone acetate. At median follow-up of 65.7 months, there was a significantly improved 5-year DFS of 74% versus 40% with the use of hormonal therapy ($P = .0001$). The 5-year overall survival was 78% in the hormone group versus 78% in the radiation therapy alone group ($P = 0.0002$) [23].

Toxicity profile

Anatomic considerations

By virtue of its anatomic location, anterior to the rectum and posteroinferior to the bladder, treatment to the prostate results in mainly acute urinary and rectal side effects. The urethra, running right through the gland, can hardly be avoided. Neurovascular bundles responsible for erectile function run alongside the right and left posterolateral apical aspects of the gland (Figure 114.1). As a result of their location, these structures receive a relatively high dose of radiation therapy and sustain most of the collateral damage from treatment. Imaging plays a primary role in locating these structures to assist in minimizing the planned dose and also maintaining precision of treatment delivery. The ultimate goal is to improve the therapeutic margin by increasing dose to the prostate, while reducing dose particularly to the bladder and rectum.

Grading toxic events

The EORTC/RTOG criteria of acute and chronic radiation morbidity are provided for all different clinical systems. Acute morbidities for lower gastrointestinal and genitourinary side effects, often cited for prostate cancer treatment, are listed in Table 114.4. The criteria

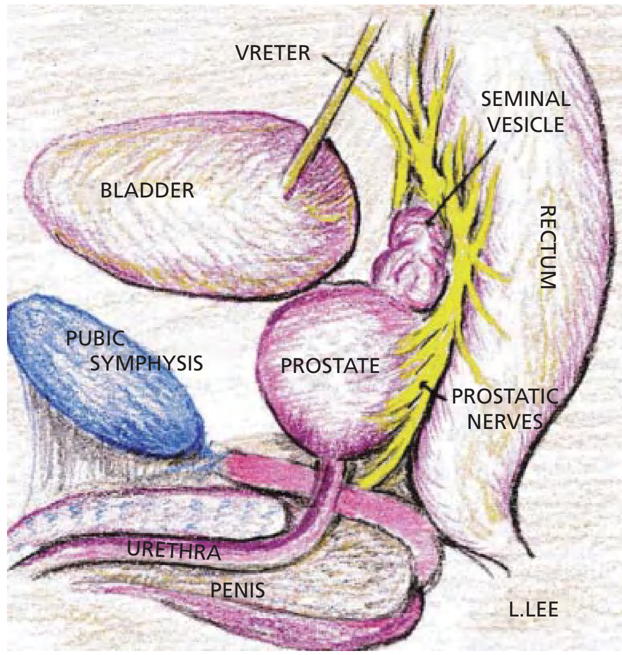

Figure 114.1 Prostate *in situ.*

Table 114.4 Radiation Therapy Oncology Group (RTOG) acute radiation morbidity scoring criteria.

Score	0	1	2	3	4
Lower gastrointestinal	No change	Increased frequency or change in quality of bowel habits not requiring medication/rectal discomfort not requiring analgesics	Diarrhea requiring parasympatholytic drugs/mucus discharge not necessitating sanitary pads/ rectal or abdominal pain requiring analgesics	Diarrhea requiring parenteral support/ severe mucus or blood discharge necessitating sanitary pads/ abdominal distention (distended bowel loops on radiograph)	Acute or subacute obstruction, fistula or perforation; GI bleeding requiring transfusion; abdominal pain or tenesmus requiring tube decompression or bowel diversion
Genitourinary	No change	Frequency of urination or nocturia twice pretreatment Habit/dysuria, urgency not requiring medication	Frequency of urination that is less frequent than every hour Dysuria, urgency, bladder spasm requiring local anesthetic (e.g. phenazopyridine)	Frequency with urgency and nocturia hourly or more frequently/dysuria, pelvic pain or bladder spasm requiring regular frequent narcotic/gross hematuria with/ without clot passage	Hematuria requiring trans-fusion/acute bladder obstruction not secondary to clot passage, ulceration or necrosis

Table 114.5 European Association for Research and Treatment of Cancer (EORTC)/Radiation Therapy Oncology Group (RTOG) criteria of late effects.

Score	0	1	2	3	4
Small/large intestine	None	Mild diarrhea; mild cramping; bowel movements 5 times daily; slight rectal discharge or bleeding	Moderate diarrhea and colic; bowel movement >5 times daily; excessive rectal mucus or intermittent bleeding	Obstruction or bleeding requiring surgery	Necrosis/ perforation fistula
Bladder	None	Slight epithelial atrophy; minor telangiectasia (microscopic hematuria)	Moderate frequency; generalized telangiectasia; intermittent macroscopic hematuria	Severe frequency and dysuria; severe telangiectasia; frequent hematuria; reduction in bladder capacity (<150 mL)	Necrosis/ contracted bladder capacity (<100 mL), severe hemorrhagic cystitis

Table 114.6 Common Terminology Criteria for Adverse Events (CTCAE) Version 4.0 grading system.

Grade refers to the severity of the adverse event:	
Grade 1	Mild; asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated
Grade 2	Moderate; minimal, local or noninvasive intervention indicated; limiting age-appropriate instrumental activities of daily living (ADL)*
Grade 3	Severe or medically significant but not immediately life-threatening; hospitalization or prolongation of hospitalization indicated; disabling; limiting self-care ADL**
Grade 4	Life-threatening consequences; urgent intervention indicated
Grade 5	Death related to adverse event

*Instrumental ADL refer to preparing meals, shopping for groceries or clothes, using the telephone, managing money, etc.
**Self-care ADL refer to bathing, dressing and undressing, feeding self, using the toilet, taking medications, and not bedridden.

for late effects are determined after the 90th day from the commencement of therapy and are listed in Table 114.5 [24]. Common Terminology Criteria for Adverse Events (CTCAE) provide similar information and are also frequently used. Version 4.0, released in May 2009 and updated in September 2009, includes a range of grades for various toxicities. The grading system ranges from 1 to 5: asymptomatic, symptomatic, severely altered function, life-threatening consequences, and death, respectively (Table 114.6). Rectal toxicities include rectal fistula, hemorrhage, mucositis, necrosis, obstruction, pain, perforation, and ulcer. Urinary toxicities include urinary fistula, frequency, incontinence, retention, tract obstruction, tract pain, urgency, cystitis and hematuria. Other adverse events that may apply to prostate cancer treatment include ejaculatory disorder and erectile dysfunction.

Table 114.7 Acute toxicity with intensity-modulated radiation therapy (IMRT) to 81–86.4 Gy (n = 772).

Toxicity	Grade	Gastrointestinal	Genitourinary
	0	568 (74%)	258 (33%)
	1	169 (22%)	296 (38%)
	2	35 (4%)	217 (28%)
	3	0	1

Table 114.8 Late toxicity intensity-modulated radiation therapy (IMRT) to 81–86.4 Gy (n = 772).

Toxicity	Grade	Gastrointestinal	Genitourinary
	0	688 (89%)	570 (74%)
	1	69 (9%)	121 (16%)
	2	11 (1.5%)	76 (9.5%)
	3	4 (0.5%)	5 (0.5%)

Morbidity data

Current NCCN practice guidelines recommend doses of 75.6–79 Gy for low-risk disease and 78–80+ Gy for intermediate- to high-risk disease. Acute toxicities were reported for 772 patients undergoing IMRT to 81–86.4 Gy between the years 1996 and 2001 (Table 114.7). These doses are at the upper end of the recommended dose spectrum and they resulted in relatively low morbidity. Most patients developed grade 0–1 acute toxicity and there was one grade 3 urinary complication of obstruction. Late toxicity is shown in Table 114.8. With a median

follow-up of 24 months, most patients had no residual gastrointestinal symptoms (89%) and many had no urinary symptoms (74%). At a median of 9 months, 1.5% had developed grade 2 rectal bleeding and 0.5% grade 3 bleeding requiring transfusion or laser cauterization. At a median of 6 months, 9.5% had developed grade 2 chronic urethritis requiring medication for symptom control and 0.5% grade 3 urethral stricture requiring dilation. Among the 540 patients who were potent prior to treatment, 52% maintained erectile function at 2 years post treatment [25]. Longer follow-up will be important for documenting chronic toxicity at these doses. For patients treated between 1988 and 2000 to 66–81Gy using either three-dimensional (3D)-conformal techniques or IMRT, CTCAE criteria were reported for a median 10-year follow-up. The 10-year actuarial incidence of grade 2 or greater gastrointestinal toxicity was 9% and of genitourinary toxicity was 15%. The use of IMRT reduced the incidence of proctitis from 13% to 5% ($P > .001$) [26].

Quality of life

A prospective study examining acute and late toxicity and QOL up to 18 months after IMRT to 76 Gy showed similar findings to the morbidity data reported above and acceptable QOL. Acute urinary grade 2 and 3 toxicity was 38% and 2%, respectively. Acute bowel grade 2 and 3 toxicity was 13% and 0%, respectively. Temporary detriment in QOL, mainly due to urinary symptoms, reverted back to initial scores by 18 months [27]. A QOL comparison of treatment with 3D-conformal therapy to 70 Gy versus IMRT to 76 Gy using fiducial markers to verify position, showed no detriment for the higher dose using IMRT at 1 and 6 months after treatment. There was actually an improvement in pain and urinary symptoms within the first month [28]. These techniques are detailed under Treatment planning (see below).

Secondary malignancies

Secondary malignancies are a rare but dreaded complication of therapeutic ionizing radiation. A secondary malignancy is characterized by occurrence within the prior radiation portal and usually has a latency of several years or longer, especially for solid tumors. The potential for developing secondary malignancies is generally greater for a younger patient because of the likelihood of longer survival compared to an older patient. SEER data comparing over 50 000 patients treated with radiotherapy and over 70 000 patients treated with surgery for prostate cancer, showed a small but statistically increased risk of developing tumors of the bladder, rectum, and lung, and also sarcoma. There was an increased relative risk of 15% for patients surviving 5 years or more, and 34% for patient surviving 10 years or more. The absolute risk of developing a secondary malignancy from radiation therapy was 1 in 290 patients, increasing to 1 in 70 for those surviving 10 years or more [29]. These data are consistent with other reports [30–33]. When brachytherapy is examined separately, the risk does not appear to be as for EBRT [31, 32]. Therefore, if otherwise reasonable, brachytherapy may be a better choice for the younger patient.

Treatment planning

Simulation details

Treatment planning begins with a simulation. The patient is positioned for the treatment and immobilization devices are used to ensure that the patient's position is reproducible on a daily basis. These may include a thermoplastic mold stretched over the pelvis and secured to the table. Various techniques to identify certain structures, such as a Foley catheter and rectal catheter, or contrast dye may be useful to define the bladder and rectal margins. Comfort measures such as a hand ring or wedge under the knees may be offered. Kilovoltage (kV) X-rays, generally a set of orthogonal films overlain with a grid, are obtained at the time of simulation and serve as the baseline for future set-up verification. Tattoos are placed on the skin at the center of the anterior and two lateral fields in order to "triangulate" the isocenter. In the traditional four-field box technique, treatment was from anterior, posterior, right lateral, and left lateral directions (Figure 114.2). Field borders were designated on the films and generally corresponded to bone landmarks, e.g. the inferior border was set at the bottom of the ischial tuberosities. Cerrobend, a lead alloy, was constructed in blocks as needed, e.g. to shield the posterior rectum based on the configuration of the rectal contrast on the film. Currently, ball bearings are placed on the tattoos and a CT scan of the pelvis is obtained instead of X-ray films. Digitally reconstructed radiographs (DRRs) are generated from the CT information (Figure 114.3).

Portal imaging

The traditional method of checking a patient's set-up during treatment is weekly megavoltage (MV) portal imaging. This involves obtaining a set of orthogonal films, using the skin tattoos to locate the isocenter. These images utilize the MV energy of the treatment itself, which provides films of poor quality, but which are generally suitable for visualizing the bone anatomy. When overlain with a grid, these images can be compared with the initial set of therapeutic quality

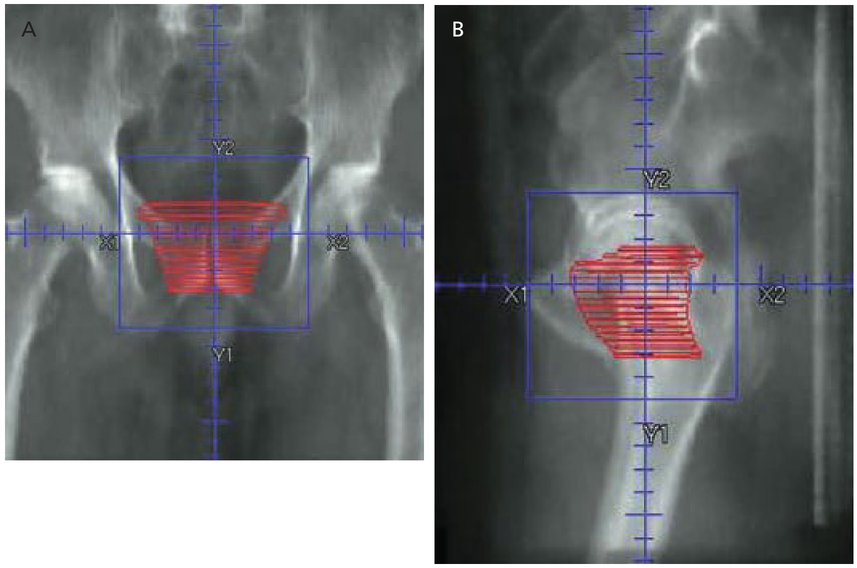

Figure 114.2 (A, B) Examples of anterior and lateral beam appearance from four-field box technique.

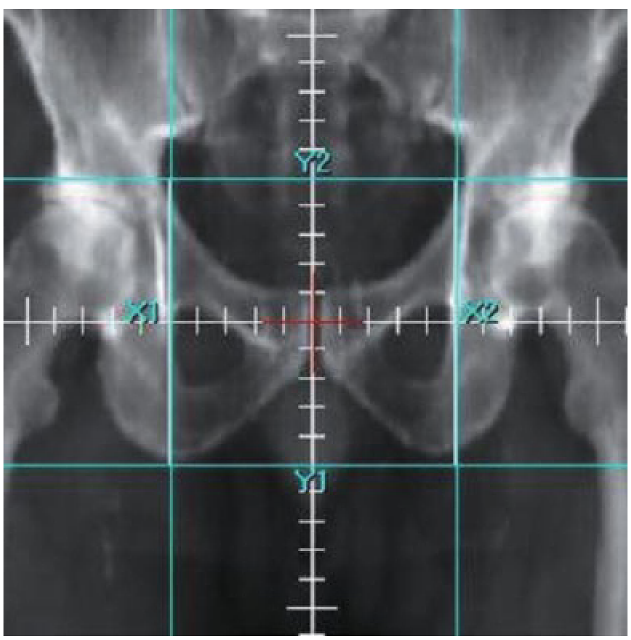

Figure 114.3 Digitally reconstructed radiograph.

simulation films or DRRs obtained at the beginning of treatment to verify the patient's position (Figure 114.4). Weekly MV portal images are the primary form of verification and continue to be used in standard practice.

Target volume delineation

The CT images are reviewed using treatment planning software, many of which are commercially available. The area of interest is outlined on each slice to generate a target volume. Target volumes generally include a gross tumor volume (GTV), a clinical target volume (CTV) which includes microscopic disease, and a planning target volume (PTV), which includes the CTV with a margin for error. For the treatment of prostate cancer, the CTV rather than the GTV is usually outlined. This includes the entire prostate gland since CT does not give enough detail to outline gross tumor. Moreover, multifocal disease is common. While the PTV usually includes the proximal aspect of the seminal vesicles, more advanced disease may warrant full coverage. The PTV is often represented by a volume that is generated by expanding the prostate volume by 1 cm in all directions. Differential margins are often used. For example, since the rectum is adjacent to the prostate with little or no room in between, this margin is often smaller, i.e. 5–6 mm. In a dose escalation study comparing 70 Gy to 78 Gy, anterior and inferior margins of 1.25–1.5 cm and posterior and superior margins of 0.75–1.0 cm were used [34]. As doses increase and treatment becomes more conformal, margins will likely shrink.

3D-conformal radiation therapy

3D-conformal radiation therapy improves upon the traditional four-field box technique (see above). CT information obtained at the time of simulation allows an unlimited variety of beams to be chosen to optimize treatment delivery. Since an increasing number of beams adds to the treatment time and patient discomfort, a typical plan might use five to seven beam angles. In a typical prostate treatment plan, beams target the pros-

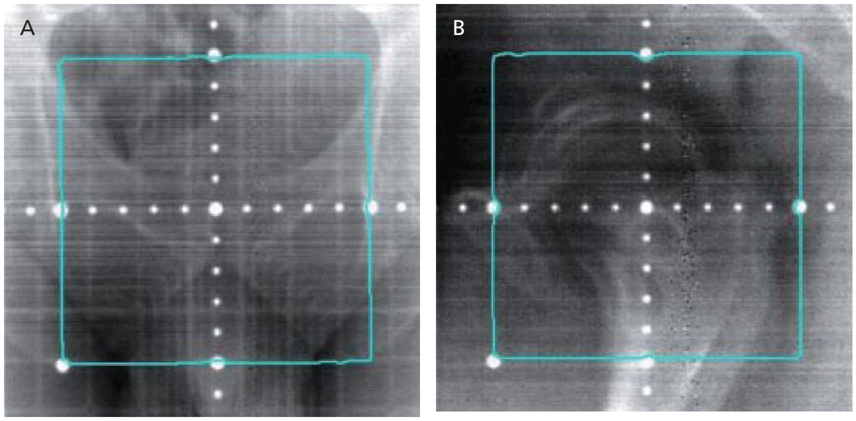

Figure 114.4 (A, B) Orthogonal portal images for prostate treatment verification.

tate while avoiding the bladder, rectum, and femoral heads (Figure 114.5). Differential weighting or adjusting the fractional dose per beam fine tunes the coverage of the target volume. Various techniques for collimation can be employed, including the use of cerrobend blocks that closely conform to the PTV (Figure 114.6). Wedges placed in front of the beam provide a dose gradient across the field in any one of four directions. These advances have paved the way for dose escalation and reduced margins.

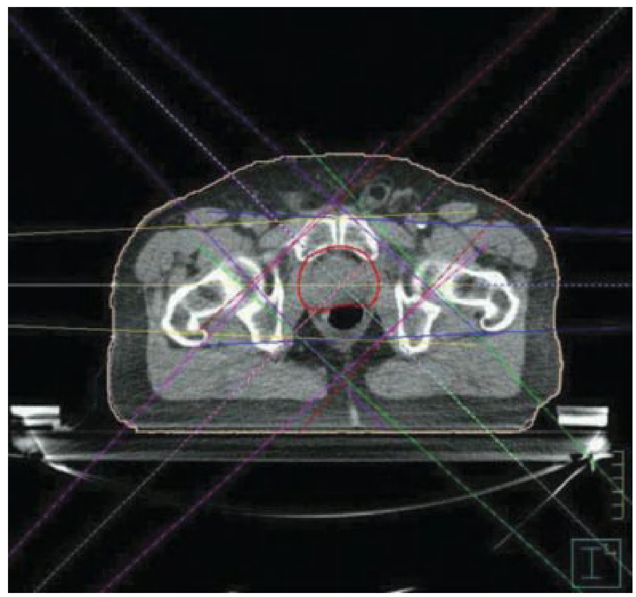

Figure 114.5 Axial slice of six-field 3D-conformal plan.

Dose escalation

A dose escalation study randomized 305 patients from 1992 to 1998 with T1–T3 disease to 70 Gy in 35 fractions via a four-field box technique or 78 Gy in 39 fractions using a six-field 3D-conformal technique [34]. Freedom from biochemical or clinical failure was significant and increased with time in favor of the higher dose: 85% versus 78% at 5 years, 78% versus 59% at 8 years, and 73% versus 50% at 10 yrs ($P = .004$). The 10-year incidence of Radiation Therapy Oncology Group (RTOG) grade 3 gastrointestinal toxicity was significantly higher with the 78 Gy dose (26% vs 13%). However, genitourinary toxicities were not significantly different between the doses, and there were no grade 4 or higher toxicities. A meta-analysis of randomized controlled trials suggested that high dose was beneficial for all risk groups compared to conventional dose treatments [35]. Furthermore, a meta-regression analysis predicted close to 100% biochemical control for doses around 90 Gy, especially for the low-risk group. Significantly higher grade 2 or greater gastrointestinal toxicity was also seen, but there was no significant difference is genitourinary toxicity [35]. It is notable that this and other dose escalation studies are unable to show a survival advantage because of the prolonged natural history of prostate cancer, with patients often dying from other causes. The issue is raised whether the improvement in biochemical control is worth the added toxicity, albeit mild.

Rectal dose–volume relationships

Rectal dose–volume relationships have been studied in detail. The percentage of rectal volume receiving 70 Gy (V70) predicts for chronic toxicity. In one study the rectal doses of 331 patients undergoing 3D-conformal radiation therapy to 75.6 Gy were analyzed. With a median follow-up of 1.6 years, a V70 of less than 25%, 25–40%, and greater than 40% resulted in grade 2 or greater toxicity rates of 9%, 18%, and 25% respectively [36]. A similar analysis was done on 163 patients treated with 3D-conformal techniques to 74–78 Gy and a median follow-up of 62 months. The 6-year rate of rectal

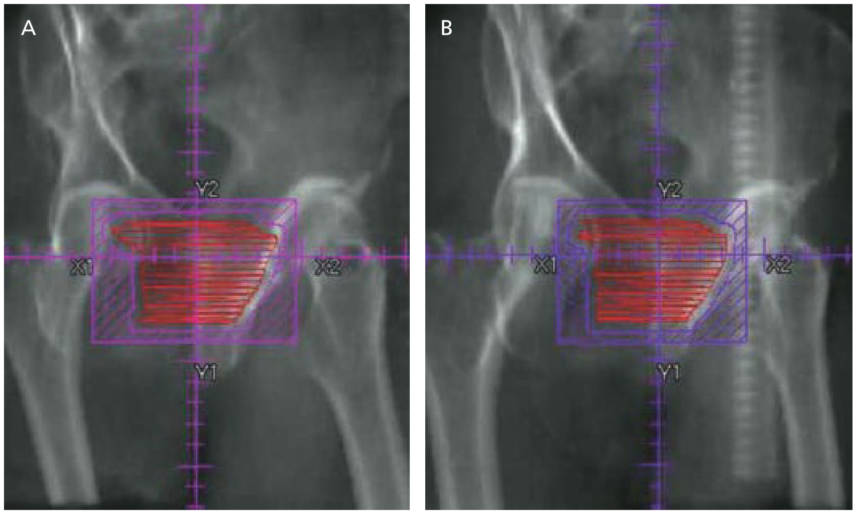

Figure 114.6 (A, B) Examples of two oblique fields of a six-field plan with blocking around planning target volume (PTV) shown in red.

complications of grade 2 or higher was 54% versus 15% for V70 of greater than 26.2% versus 26.2% or smaller, respectively [37]. Further analysis showed that even at lower doses, high volume resulted in increased toxicity. There was a 50% or higher incidence of grade 2 toxicity or worse within 2 years if 80% or more of the rectal wall was exposed to 32 Gy [38]. These data allowed limits to be set for future treatment planning. These limits are generally achievable with IMRT.

Intensity-modulated radiation therapy

IMRT expands on the simple wedges used to provide a gradual dose gradient across a field. This technique utilizes a series of miniature sliding doors, called mutlileaf collimators (MLCs), which differentially attenuate the radiation beam. Since the MLCs can remain open or closed in innumerable positions, the ability to collimate the radiation beam is vastly improved.

Treatment delivery

Set-up uncertainty and rectal variability

Traditional methods of orthogonal portal images and skin tattoos lead to margin uncertainties as large as 1–2 cm [39]. Positioning based on bone anatomy is clearly limited in its ability to reproduce organ position. This could be addressed by increasing the margins, but in the area of the prostate, increased margins lead to increased complications [40]. A study of weekly CT scans on six patients showed significant interfraction target position variability. Estimates of PTV margins in the anteroposterior (AP), craniocaudal (CC), and mediolateral (ML) directions to cover the CTV with 95% certainty were: 12.4 mm, 10.3 mm, and 5.6 mm, respectively, for the prostate, and 13.8 mm, 8.6 mm, and 3.9 mm, respectively, for the seminal vesicles [41]. Rectal variability is reproducible and appears to be responsible for most of the variation [42, 43]. For example, the prostate may be located posteriorly if a patient has diarrhea and less rectal filling. On the other hand, the prostate may be located more anteriorly if the patient has proctitis or tends to tense the pelvic muscles during treatment. Therefore, corrections are not universal and ideally should be tailored to the individual.

Bladder volume

The bladder appears to contribute less to target position variability than the rectum [41]. An empty bladder is more reproducible than a full bladder, but allows a larger volume of bladder to be exposed to the high-dose area. Conformal treatments such as IMRT can reduce bladder volume significantly. Patients can also be treated with a full bladder, but this state tends to be less reproducible with variable bladder volumes from day to day. In addition, the patient may tense the pelvic muscles to postpone urination, which may lead to changes in prostate position [39]. However, if the patient can train himself to have a consistently full bladder for treatment each day, the major advantage is that a significantly smaller volume of bladder will be in the high-dose area.

Intrafraction error

Intrafraction error, which occurs during a single treatment, dramatically increases the complexity of target motion. While breathing can result in predictable sinu-

soidal patterns, motion in the region of the prostate has been described as "slow drift" or "sudden transient" due to acute changes in colonic content [44]. A study of 21 patients was conducted where a CT was done before and after treatments to determine the intrafraction error. Prostate drifts of greater than 5 mm were found in 12% of all fractions, and a margin of 6 mm was determined to compensate for these changes [45]. These unpredictable movements suggest a benefit to localization and tracking the prostate during treatment. Image-guided radiation therapy includes various methods to achieve these goals.

Methods for image-guided radiation therapy

Placement of fiducials

Fiducial markers are usually made out of metal and vary in size and configuration. Commonly used fiducials are made of gold and can be shaped like pellets or coils. For the prostate, gold fiducials usually measure less than 1 mm in diameter and a few millimeters in length. A textured surface, as with the coils, can reduce migration. Preparation for the procedure includes an enema the night before and on the morning of the procedure. Antibiotics are prescribed prophylactically to prevent infection. For example, ciprofloxacin 500 mg may be taken twice a day for 3 days. When the implantation site is identified on rectal ultrasound, approximately 1–3 mL of lidocaine 1% is injected for local anesthesia. The fiducials are placed into an introducer needle and then placed into the site with a stylet. Toxicity is generally minor, including bleeding such as hematuria, hematospermia, and hematochezia; generally lasting for a day or two. There may be mild rectal discomfort, which is usually improved with acetaminophen. Sepsis is also a possibility, but rare.

On-board imaging

A logical advance in weekly portal imaging is to use therapeutic quality X-rays so that the images are closer in quality to the simulation films. A kV X-ray tube mounted opposite an image detector is conveniently added to any existing linear accelerator, and is otherwise known as on-board imaging (OBI). The high resolution allows for better visualization of skeletal anatomy and also of fiducials implanted in soft tissues. An additional benefit of this system is a significantly lower dose of radiation, about 0.01–0.1 cGy/film; MV imaging gives an estimated 4–16 cGy/orthogonal pair [46]. The lower dose given with kV images makes daily imaging for localization more reasonable. In order to make the process of daily filming time efficient, an electronic portal imaging device (EPID) is often used rather than traditional film processing. In addition, a kV fluoroscopy unit can be used to localize fiducials at the start of treatment, and then can provide realtime tracking of the fiducials during treatment [47]. The treatment may be held if the fiducials move out of a predetermined volumetric range, then restarted when the fiducials move back into range. This process is referred to as gating and can be used with other realtime tracking techniques.

CT-based verification

Since CT-based planning has become the norm for 3D-conformal and IMRT planning, using CT for verification is a logical advance. CT provides soft tissue detail and a 3D aspect to verification, a clear improvement upon the traditional 2D orthogonal films. CT-based verification may utilize either kV or MV energies. The pros and cons of these are similar to those for the respective X-ray films. The images can also be obtained using either a helical beam or a large field cone beam [48]. The helical beam opposite the detector makes multiple rotations around the patient in order to obtain the necessary data to construct the images. The large field cone beam is opposite a flat panel detector, which can acquire the data in a single rotation [49].

Cone-beam MV CT utilizes the treatment beam itself to provide the images. The system is easy to implement since it only requires an EPID mounted onto an existing machine. The wide field beam is subject to divergence and scatter, which reduces the quality of the images. The dose to the patient is relatively high, approximately 5–15 cGy/scan [50]. Helical MV CT (TomoTherapy, Madison, WI, USA) is a combined CT scanner and linear accelerator that utilizes the continuous motion of the gantry and couch of a diagnostic helical CT scanner to provide both imaging and treatment. It exposes the patient to less radiation, about 1–2 cGy [48], but it may take longer to acquire the necessary images since multiple rotations around the patient are needed to complete the process. As a result, the images are more likely to show motion artifact due to respiration. Although poor relative to kV images, the image quality of MV CT is sufficient for positioning corrections based on skeletal anatomy. A primary advantage to using MV CT is the reduced artifact from orthopedic hardware [49]. This can be useful for patients with a hip prosthesis. It is particularly useful for visualizing fiducials because of the lack of a star-like artifact that can be present in kV images. Compared to kV imaging, the disadvantages include poorer anatomic image quality and increased dose to the patient.

A kV CT system provides excellent resolution since the CT is of diagnostic quality and is actively under

investigation for advances in image adaptive techniques. For example, head and neck tumors have the potential to change rapidly in size during treatment and are often surrounded by multiple soft tissue organs of interest, such as the parotid glands and spinal cord. The CT information used for verification can be used not only to re-align the patient, but also to replan the treatment if there are major anatomic differences. The system may be more difficult to implement than MV CT since it requires a CT unit separate from the linear accelerator. Moreover, the patient must remain immobilized in the treatment position for both scans. With a 180º couch rotation, the patient can be moved from the linear accelerator to the mobile CT unit, which then can be moved into position for the scan [48].

kV cone-beam CT can offer several advantages, including superior imaging as well as realtime tracking ability from the fluoroscopic capability. A kV unit is mounted 90º from the gantry of the linear accelerator and opposite an X-ray detector. Sub-millimeter accuracy has been reported with this system. Since the image registration requires a full rotation over a period of about 1 min, the system can still be subject to inaccuracies from breathing and other motions [48]. The system is well-suited for intracranial radiosurgery but may require gating techniques for lung tumors.

Ultrasound verification

The B mode Acquisition and Targeting System (BATS) is a portable ultrasound localization device. CT data from the simulation are transferred to the system. Ultrasound imaging is performed prior to treatment and matched to the original CT images. If the images differ, the system will then produce the necessary couch shifts in order to realign the patient to match the ultrasound realtime images [51]. Despite the ease of implementation, accuracy may not be as high as with CT verification techniques due to the lower image quality and the potential for the probe itself to move the prostate [52, 53]. Therefore, the technique is more dependent on user skill and interpretation of images. One major disadvantage is the lack of tracking ability.

Electromagnetic field tracking

A major advantage to electromagnetic field tracking is the lack of additional ionizing radiation. The Calypso 4D Localization System (Calypso Medical Technologies, Seattle, WA, USA) requires the implantation of beacon transponders, which carries the same risks as implantation of fiducials. Although anatomic images are not produced, the corrections are objective and do not require user skill and interpretation.

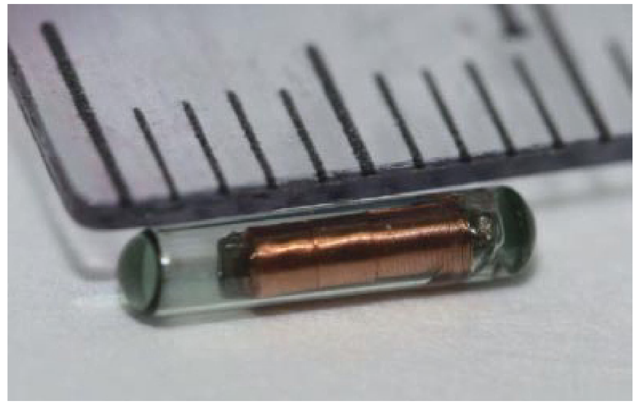

Figure 114.7 Close up of Calypso (Calypso Medical Technologies, Seattle, WA, USA) beacon transponder next to millimeter ruler demonstrating internal electromagnetic coils.

Transponder placement

The beacon transponder contains a miniature electrical circuit sealed in a glass capsule, measuring 1.85 mm in diameter and 8 mm in length (Figure 114.7). Like fiducials, transponders are implanted into the left lobe, right lobe, and apex of the prostate gland via 14G introducer needles. Transponders may migrate soon after the procedure. The mean of the standard deviation of intertransponder distance variation measured at 4 days after implantation was 1.3 mm and 0.8 mm at 14 days after implantation [54, 55]. This compares favorably to gold seed markers, for which the mean of the standard deviation of intermarker distance variation measured throughout the course of treatment was 1.0 mm [56]. Like fiducials, beacons may become lost due to implantation into the urethra or into the venous plexus going to the seminal vesicles, but in the majority of cases they are quite stable. Another potential route for loss of a transponder located between the prostate and rectum could be through the rectal wall. In 60 patients, one study reported loss of one beacon via the urethra and one to the venous plexus [54]. The mean standard deviation of the intertransponder distances over a period from 4 days post implant through the last radiation fraction was 0.8 mm. There was no significant difference in the stability of the transponders placed at the base versus the apex [57]. Overall, these data demonstrate significant stability of the geometry of implanted transponders throughout an entire course of EBRT, which is typically 8–9 weeks.

Simulation procedure

The patient then returns for simulation about 1–2 weeks later. Patients are supine for the simulation, and CT scan slices of 1–1.5 mm of the pelvis are obtained. Previous

work has shown that transponder locations are known to within 0.7 mm using thin-slice CT [58]. Immobilization devices are generally minimal. The treatment planning CT is done as usual and the isocenter is placed in the middle of the beacons. Then the coordinates of the beacons in reference to the isocenter are entered into the Calypso software.

Localization

When the patient is ready to be treated, the beacon transponders are located, which includes identifying their positions in 3D space relative to each other. An electromagnetic array, containing source and receiver coils, is placed over the patient. The source coils emit an electromagnetic signal that excites the beacon transponders. The signal is then turned off, and the receiver coils then detect the signal emitted from the transponders. Each transponder has a unique resonant frequency so that each one can be distinguished from the others. A best geometric fit is determined to match the coordinates from the simulation data entered previously into the system. This correction is translated into couch movements, which will move the patient to the corrected position. When a patient is set-up with skin tattoos and verified with the Calypso system, most of the corrections are within 1.5 cm, but approximately 10% are greater than 1.5 cm, demonstrating the value of localization. Compared with the kV X-ray localization methods, the accuracy of the Calypso system is less than 1.5 mm.

Tracking

For tracking, position updates are obtained at 10-Hz frequency and the differences between the actual isocenter and the calculated isocenter are displayed graphically, providing the fourth dimension of time (Figure 114.8). If the movement is outside a set threshold of, for example, 3 mm, then the operator has the option of stopping the treatment until the target is back in alignment, or performing a couch correction if needed. Most of the lateral shifts are within 5 mm but about 8% exceed 1 cm. Large lateral shifts tend to be more common in large

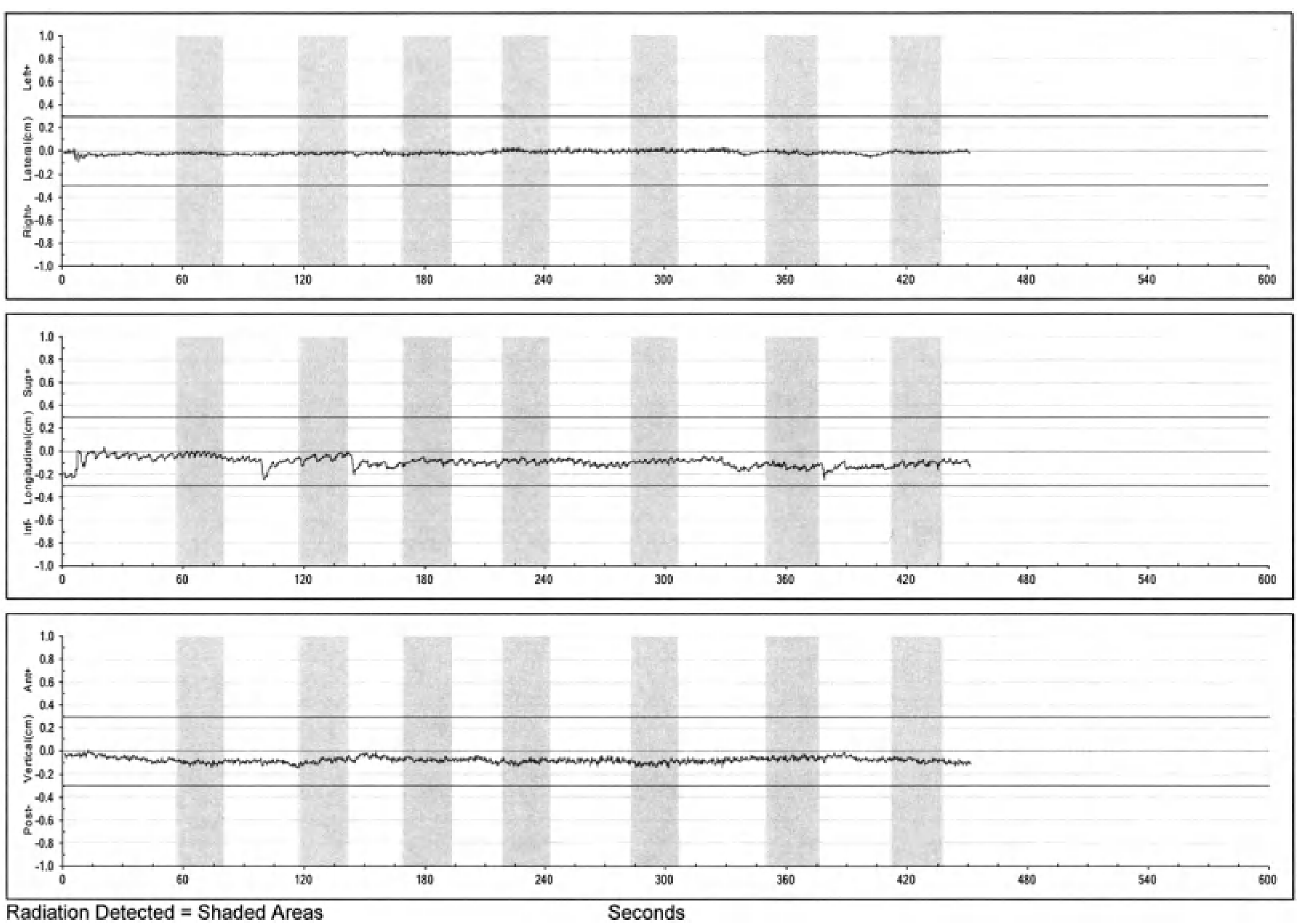

Figure 114.8 Calypso session report showing patient remaining within set threshold; gray areas represent when the radiation is turned on.

patients. Superoinferior shifts tend to be within 5 mm, suggesting relatively limited movement in these directions. Anteroposterior shifts, depending on rectal contents, are most common and are usually within 1.5 cm. Tracking data show that motion of more than 5 mm for longer than 30 s occurs during 15% of the fractions [57]. With the exception of a slow posterior shift associated with relaxation, many of these movements are unpredictable and pose a challenging problem for future improvements and developments.

Conclusions

Image-guided radiation therapy offers a wide range of techniques, which allow an improved therapeutic ratio in the treatment of prostate cancer by increasing the dose to the tumor for better tumor control, while reducing the dose to adjacent critical organs for lower morbidity. This goal drives much of the research performed in the field of radiation medicine and promises to improve outcomes and QOL for patients.

CHAPTER 115

High-Intensity Focused Ultrasound of the Prostate

Christian G. Chaussy[1] & Stefan Thüroff[2]

[1]Department of Urology, University of Regensburg, Regensburg, Germany

[2]Department of Urology, Klinikum Muenchen-Harlaching, Munich, Germany

Introduction

For more than 70 years it has been well known that tissue can be destroyed from a distance by high-intensity focused ultrasound (HIFU). However, clinical implementation of this technology was delayed due to the lack of reliable control. Special software, transrectal ultrasound (TRUS), and magnetic resonance imaging (MRI) now allow for realtime control and monitoring of HIFU treatment. Therefore, treatment with HIFU can now be extended to different surgical areas as an extracorporeal method, which allows the noninvasive destruction and removal of tissue without a formal surgical procedure. Increased experience and literature on HIFU has led to increasing acceptance and validation of transrectal HIFU treatment of prostate cancer internationally. Long-term results have been published, but as yet these do not extend to 10 years [1, 2].

In addition to the clinical application of HIFU for prostate cancer, there are currently several clinical trials ongoing for the treatment of benign and malignant tumors, such as kidney, breast, liver, thyroid, brain, uterine fibroids, and glaucoma.

Principle of high-intensity focused ultrasound

HIFU for local tissue destruction was first used in 1942 [3]. High-energy ultrasound parabolically focused on tissue leads to mechanical alteration of cells and changes in biologic structures (Figure 115.1). Three different mechanisms can be observed: mechanical, cavitation, and thermal effects.

Mechanically, the negative pressure of the ultrasound wave forms cavitation bubbles within the tissue. The cells increase in size to the point at which resonance is achieved. High pressure of about 20 000–30 000 bars develops when the bubbles suddenly collapse, causing instant mechanical cell death.

The thermal effect is caused by the absorption of ultrasonic energy in tissue. The temperature increase in tissue depends on the absorption coefficient of the tissue, and the size, shape, and temperature sensitivity of the heated area. The biologic changes caused by the heating depend on the temperature level and duration of exposure. A "thermal dose," which exceeds a certain threshold, causes irreversible tissue damage in the form of coagulation. For thermal doses below the threshold, the effect of temperature depends upon the tissue sensitivity [4].

During HIFU, the ultrasound generates a very high intensity in the focal area, while the surrounding tissue is only slightly charged. Focused ultrasound waves causing high temperature within a few seconds (70–c. 100°C) destroy the tissue in a circumscribed area, while surrounding areas remain unharmed. The tissue volume that is destroyed by a single ultrasonic beam is called the "primary" lesion. In order to create lesions in larger areas, multiple lesions have to be added to the primary lesion (Figure 115.2). This can be achieved by mechanically moving the energy source or in the case of an existing "phased array," electronically altering the focal point [4–6].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

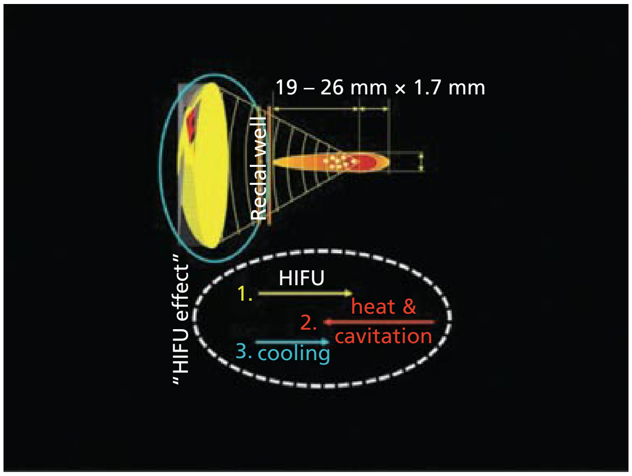

Figure 115.1 Physical principle of high-intensity focused ultrasound (HIFU).

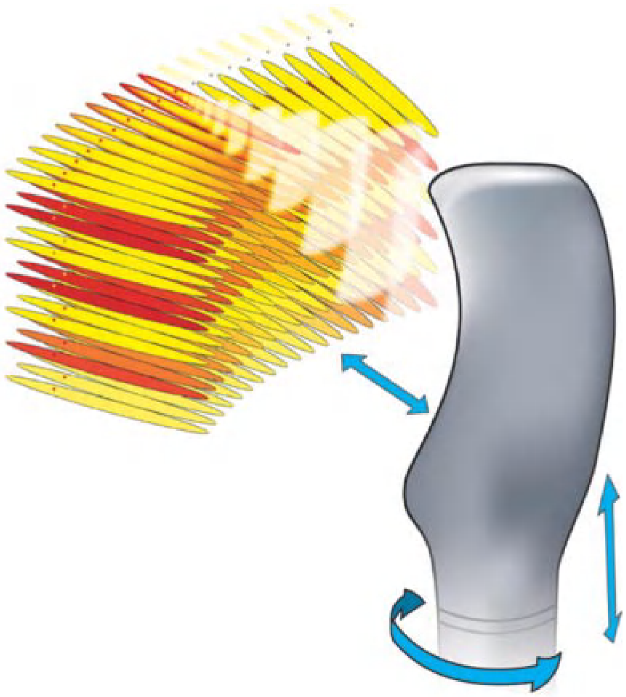

Figure 115.2 Multiple lesion distribution.

Technology

Several parameters are essential to the development of an HIFU system for a specific application. The most difficult technical decisions concern the selection and design of the piezoelectric energy converter, the parameters of ultrasound treatment (megaHertz, Watts), and the imaging system and localization during treatment (TRUS, MRI).

The therapeutic ultrasonic energy transducer is characterized mainly by the operating frequency and the geometric and physical dimensions (Figure 115.3). Modern piezoelectric systems can be operated with energy density, reproducibility, and long-term stability sufficient to meet the requirements of the therapy. These systems also allow the production of geometric shapes to align them to different anatomic requirements [7].

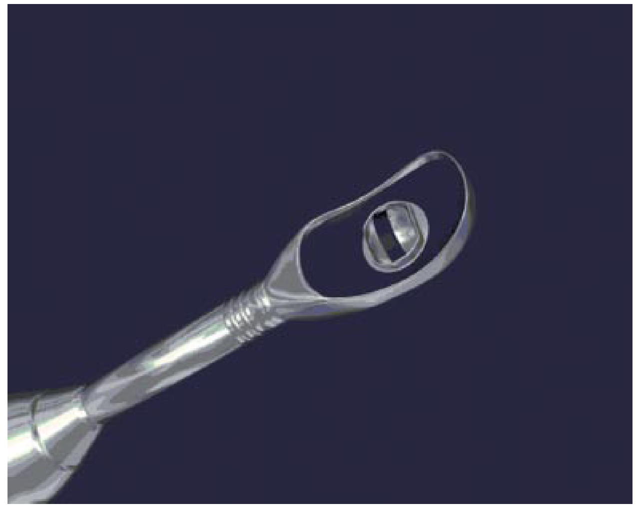

Figure 115.3 Applicator.

Current standard urologic applications use HIFU transducers with a fixed focal point that can be moved mechanically to treat large tissue volumes (Figure 115.4). Future applications, however, may use "phased-array transducers," that the focal point can be moved without changing the position of the applicator [8, 9].

The main parameters of the ultrasound treatment are the acoustic intensity, duration of application, interval of the pulses, lateral distance between elementary lesions, as well as the longitudinal displacement of the energy source when treating multiple lesions. To find the ultrasound parameters that are required for treatment of the prostate, *in vitro* and *in vivo* experiments have been performed, as well as computer simulations [10–12].

MRI is the technique of choice to assess the effectiveness of HIFU treatment and to perform realtime temperature measurements. The extent of necrosis on gadolinium-enriched T1-weighted images appears as a clearly visible hypodense zone [13]. MRI is used in extracorporeal HIFU treatments for localization and monitoring of effectiveness [13, 14], and allows for the measurement of temperature changes during HIFU treatment [13]. A few studies have used magnetic resonance elastography (MRE) to investigate the effects of temperature-induced tissue ablation by measuring the mechanical changes in the lesion [15, 16]. HIFU-induced lesions are temporarily seen as hypodense areas in diagnostic ultrasound [17]. However, the real extent of the primary lesion cannot be precisely defined in each case.

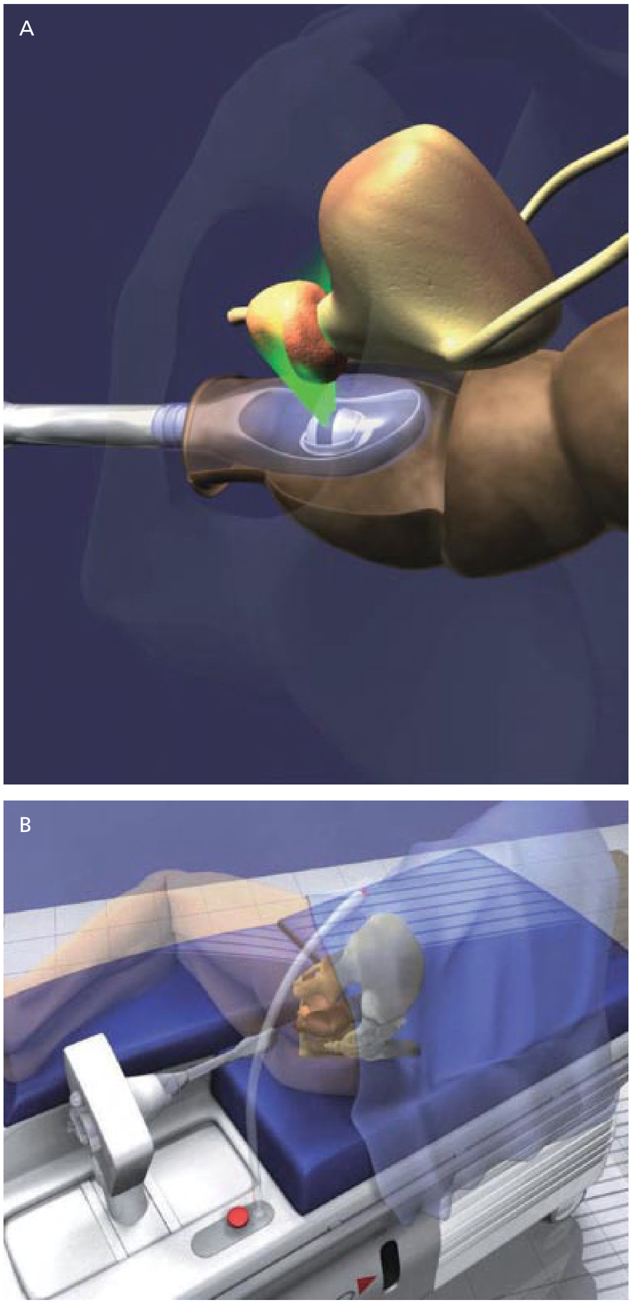

Figure 115.4 (A) Probe positioning. (B) Patient positioning during treatment.

Further characterization techniques based on ultrasound, contrast-enhanced Doppler [18] or different techniques to assess the acoustic behavior of tissues have been proposed to determine the extent of HIFU-induced lesions [19]. Based on a 14-year experience with transrectal HIFU in prostate cancer, it is evident that TRUS can be employed for safe and reproducible HIFU treatment even without "realtime" temperature measurement (Figure 115.5).

Experimental models

The HIFU-based destruction of tissue has been studied in various experimental tumor models. To study the HIFU effect *in vivo*, experiments have been performed on mouse glioma [20], hamster medulloblastoma [21], and the rat Morris hepatoma [22, 23]. DUNNING R3327, as well as AT2 and AT6 carcinomas with high metastatic potential [24, 25], implanted in rats have been studied as models of prostate cancer.

In vitro [26, 27], *ex vivo* [26, 28], and *in vivo* [14, 27, 29] experiments were also performed to study the treatment possibilities with HIFU for kidney tumors. These animal studies provided evidence that cancerous tissue can be destroyed with HIFU without inducing metastasis [25]. Transrectal HIFU for treatment of the prostate was confirmed in experimental canine models [30, 31].

Treatment of bladder cancer

In the 1990s a device, Pyrotech, was developed that allowed the destruction of superficial bladder tumors by percutaneous HIFU [32, 33]. While both experimental and clinical studies confirmed the feasibility of this application, the project was abandoned because of lower success and higher costs in comparison with endoscopic surgical procedures.

Treatment of kidney cancer

After initial animal studies, the application of HIFU for percutaneous management of renal carcinoma in humans is now in the early stage of clinical development. Pilot studies have shown necrosis and volume reduction after HIFU treatment. Treatment of upper pole renal tumors is difficult due to the absorption of ultrasound energy through the ribs [34, 35]. Experiments are ongoing o solve the main problems, e.g. respiratory movement of the kidney, high blood flow which correlates with cooling and shadowing of the ribs. Despite such limitations, preliminary experiments have demonstrated the feasibility of HIFU as a noninvasive treatment of kidney tumors. Promising studies of intra-abdominal or laparoscopic application of HIFU suggest a solution to these problems.

Treatment of other organs

Besides clinically established transrectal HIFU for prostate cancer, there are several additional HIFU applications (pancreatic cancer, thyroid cancer, brain tumors, bone sarcoma) which are mostly MR controlled. HIFU for benign diseases, such as prostate adenoma or glaucoma, is rarely used because of better and more economic surgical alternatives.

Figure 115.5 Control screen with realtime transurethral ultrasound image overlaid with virtual high-intensity focused ultrasound.

Treatment of prostate cancer

HIFU devices

During recent years transrectal HIFU for prostate cancer has found its way into routine clinical practice with approximately 30 000 patients having been treated with this technique. Initial attempts to treat benign prostatic hyperplasia (BPH) with HIFU have proved less successful [36]. Two devices have been developed for the treatment of prostate cancer. Initial results for Sonablate® (Focus Surgery Inc., Indianapolis, IN, USA) were reported in 2002 [6]. Treatment success with Ablatherm® (EDAP TMS SA, Vaulx-en-Velin, France) in prostate cancer was reported in a European multicenter study in 2003 [37, 38]. The authors reported separately about their experiences in well-defined patient groups and established, on the basis of these results, standardized procedures and protocols for patient management (see below).

Ablatherm equipment

The Ablatherm device has a treatment module that includes the patient's bed, the probe positioning system, the ultrasound power generator, and the cooling system for preservation of the rectal wall (Figure 115.6). There is also a treatment and imaging endorectal probe that incorporates both a bi-plane imaging probe working at 7.5 MHz and a treatment transducer focused at a maximum of 45 mm and working at 3 MHz. Hence, this one probe can be used for all prostate sizes and indications. The transducer has a variable focusing and rectum distance length. Realtime rectal wall control is present; automatic applicator adjustment towards the rectal wall and multiple security circuits exclude accidental focusing on the rectal wall in order to avoid rectal injury. In 2005, modifications were made to the Ablatherm device to incorporate integrated imaging.

Sonablate equipment

The Sonablate system does not include a dedicated bed. Treatment is performed with the patient in the lithotomy position under general anesthesia. Several treatment probes are available and the one used is selected according to the position of the focal point. There is no dual frequency probe that can operate at 3 MHz during the treatment phase and 7.5 MHz for visualization of the gland. Instead, treatment parameters have to be changed with each parabolic applicator for each treatment layer. For a 25 mm or 45 mm focal length probe, the lesion achieved is 10 mm in length × 2 mm in diameter, while for a split beam performed with a 30, 35 or 40 mm focal length probe, the lesion is 10 mm × 3 mm [6]. In addition, the probe is chosen according to the prostate size, with larger glands requiring deeper penetration. Treatment is usually conducted in three consecutive

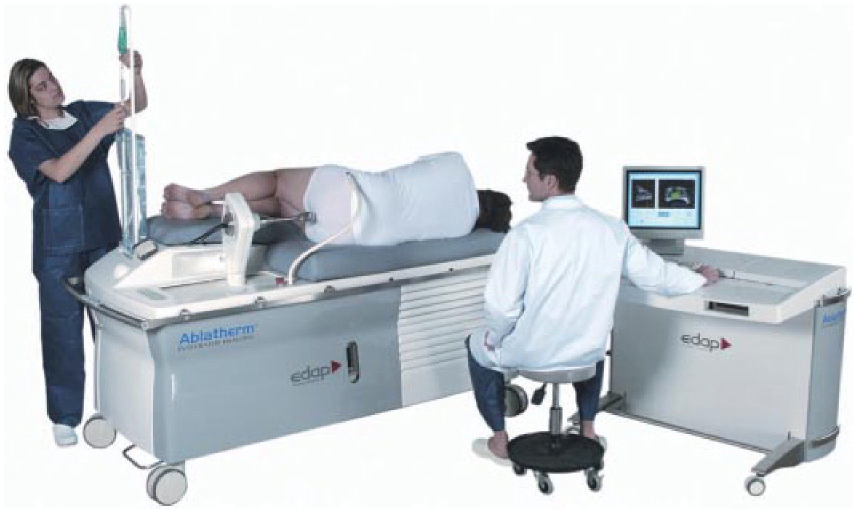

Figure 115.6 Clinical set-up of Ablatherm® (EDAP TMS SA, Vaulx-en-Velin, France).

coronal layers, starting from the anterior prostate and moving in a progressive manner from the apex to the base. As one probe integrates two different twistable parabolic piezoapplicators, there is usually at least one change of probe during the process. No realtime rectal wall distance control is present, leaving it to the operator to perform manually-guided rectal wall orientated HIFU treatment in the peripheral zone, the most likely location of a prostate tumor.

Indications and contraindications

In general, HIFU is indicated for patients with localized prostate cancer (stage T1–T2 N0M0, Gleason score 1–3) who are not candidates for surgery due to their age, general health status, a prohibiting comorbidity, or their decision against radical prostatectomy. However, the indications have been expanded based on clinical experience to include: partial therapy in unilateral low volume, low Gleason score tumors [T1–2a Nx/0M0, prostate-specific antigen (PSA) <20 ng/mL); salvage therapy in recurrent prostate cancer after radical prostatectomy, radiotherapy, or hormone ablation (all T Nx/0M0, all Gleason score/PSA); and advanced prostate cancer as an additional neoadjuvant debulking process (T3–4 Nx/0M0, all Gleason score/PSA).

Other nonsurgical treatment options for localized prostate cancer, such as cryotherapy or brachytherapy, cannot generally be repeated in cases of local recurrence. In comparison, HIFU treatment can not only be repeated but can also be used as a salvage therapy.

A basic contraindication for both devices has been a gland size of larger than 40 mL due to the focal length of the HIFU transducers. However, studies with Ablatherm have shown that larger glands can be downsized through transrectal resection of the prostate (TURP) and therefore a gland size of larger than 40 mL is no longer regarded as contraindication. Contraindications for both devices are a history of rectal fistula as there may be incomplete healing of the fistula, as well as a reduced vascular blood supply to the damaged tissues, making them more prone to injury than normal tissue. Obviously, patients with significant rectal stenosis or rectal amputation are not candidates for HIFU since the probe cannot be placed in the rectum.

Procedure

TURP before HIFU allows the removal of any reflecting/deviating calcifications, abscesses, intravesical middle lobes, and large (>40 mL) adenomas. The generation of a cavity and its subsequent compression by the rectal balloon increases the accessibility of the HIFU waves to the remaining gland (Figure 115.7). TURP should be performed radically and not leave larger adenoma parts [39, 40]. Furthermore, there should be extremely wide resection of the bladder neck and trigonum. This reduces the risk of bladder neck stenosis caused by prostate gland shrinkage after HIFU. The rectal balloon that covers the HIFU probe is then able to “squeeze” the gland to stretch and flatten the rectal wall and to fix it into position. TURP before HIFU has been a standard procedure for most users since 2000 (see below). For most prostate sizes (85%), TURP is performed at the same time as HIFU. Only for glands larger than 40 mL (15%) is TURP conducted 1 month prior to HIFU. In salvage HIFU, TURP is minimal or only a bladder neck incision is performed. In salvage therapy after radical prostatectomy, HIFU is performed without any additional endoscopic intervention.

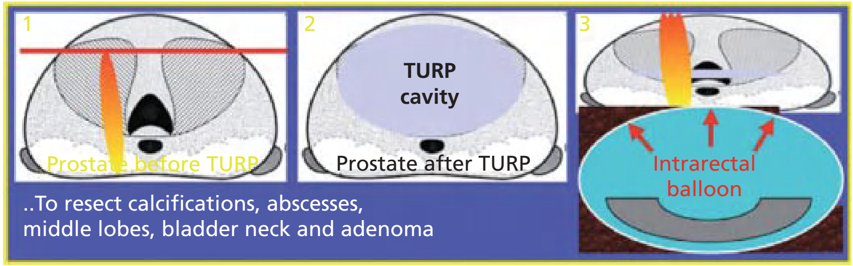

Figure 115.7 Principle of transurethral ultrasound (TURP) before high-intensity focused ultrasound.

Treatment parameters

As mentioned, the treatment parameters that are important for effective tissue coagulation include the power setting (W), piezoelectric frequency (MHz), shot duration, as well as the delay between shots and the number of shots per prostate volume (dose). A delay between shots is necessary to avoid significant accumulation of cavitation bubbles in the tissue. The length and diameter of the lesion to be generated in the prostate need to be considered in treatment planning, as well as the possibility of adapting the treatment parameters to different tissue types (untreated, preirradiated or HIFU pretreated). Consequently, three software modifications facilitate the application of different levels of energy.

Impact on serum prostate-specific antigen

The European multicenter study reported results 1 year after HIFU treatment of 402 patients with localized prostate cancer (T1–2/N0–x/M0) treated between 1995 and 1999 [38]. In total, 87.2% of control biopsies were negative. Stratified according to the prognostic risk, 92.1% were negative in the low-risk group (Gleason score < 7),; 86.4% in the medium-risk group (Gleason score 7), and 82.1% in the high-risk group (Gleason > 7). The PSA nadir was generally found 3–4 months after HIFU treatment. PSA after treatment was significantly influenced by the prostate volume in relation to the completeness of the HIFU treatment. PSA remained stable after treatment during the mean follow-up of 407 days.

Effects on prostate tissue

In a clinical study in which a partial HIFU treatment was performed 1–2 weeks before radical prostatectomy, the efficacy of HIFU was histologically confirmed. The prostate was histologically analyzed after its complete removal. HIFU had been applied to the sites where positive tissue biopsies had been found. The histologic examination of the samples showed a sharp demarcation between the HIFU-treated and -untreated areas, and in the treated areas complete necrosis was found [41].

As mentioned above, the extent of tissue damage caused by HIFU can be determined by gadolinium-enhanced MRI. The treated area appears as a hypodense zone surrounded by a strong 3–8-mm peripheral rim. This corresponds to histopathological findings characterized by a core of coagulation necrosis surrounded by a peripheral zone of inflammation. The treatment-induced MRI changes usually disappear within 3–5 months and the HIFU-induced contraction of the tissue after about 6 months results in small prostates of approximately 5 mL [42].

Efficacy

Summaries of the efficacy and side effects are given in Tables 115.1 and 115.2. In a series of 120 patients with localized prostate cancer and PSA values of less than 10 ng/mL, cancer-free survival rates were examined. These patients were not suitable for radical prostatectomy and had a life-expectancy of 10 years [2]. The calculated cancer-free 5-year survival rate for the average patient population was 76.9%; this was significantly increased to 85.4% in highly differentiated tumors (Gleason score 2–6) compared to 61.3% in poorly differentiated tumors (Gleason score 7–10). There was no significant difference in survival rates calculated in terms of prostate volume or number of positive biopsies. The nadir PSA, which is a basic prognostic factor for the theoretical 5-year survival, was less than 0.5 ng/mL and was found in 86% of the patients.

Blana *et al*. reported a study of 140 patients with localized prostate cancer [1]. These patients had a baseline PSA of 15 ng/mL or less and a Gleason score of 7 or lower. TRUS biopsies 6 months following HIFU treatment were negative in 93.4% of these patients. The mean PSA nadir was 0.07 ng/mL and the PSA was stable at 0.16 ng/mL over a mean observation period of 22 months. In 77% and 69% of patients, there was no biochemical relapse after 5 and 7 years, respectively. Although a satisfactory “cure” rate in patients with low- and medium-risk disease has been observed with HIFU

NR, not reported.

as monotherapy, combination therapy should be considered for patients with high-risk disease (see below).

In this study, no severe incontinence (grade II–III) was found. Transurethral resection during the follow-up period was required in 12% due to urinary obstruction. In 47.3% of patients, potency was maintained and there were no reports of significant changes in International Prostate Symptom Score (IPSS). The 5-year survival rates in this study correspond to those in the large series of standard treatments of localized prostate cancer [43–50] (Tables 115.1 and 115.2).

Combination therapy

TURP plus HIFU

The most commonly observed side effects of HIFU for prostate cancer include prolonged voiding dysfunction and retention caused by edema, necrosis or bladder outlet obstruction. To reduce the time of urinary diversion and the postoperative morbidity (sludging, obstruction, infection) studies were undertaken to observe the effect of a combination therapy (HIFU and TURP). In 30 patients with localized prostate cancer a one-stage (under the same anesthesia) combination therapy with TURP and HIFU was performed. The mean operative time was 2 h 48 min. The transurethral catheter time was 2 days and the mean hospitalization 3 days. After 6 months, control biopsies were negative in 80% of patients and the median PSA was 0.9 ng/mL. The mean post-treatment IPSS (PIPSS) was 6.7, compared with a pretreatment score of 7.5. Potency was preserved in 73% of patients who had reported no erectile dysfunction before treatment [39].

The benefit of a combination of TURP and HIFU was demonstrated in a series of 271 patients with prostate cancer and an initial PSA of less than 15 ng/mL [40]. Of 271 patients 96 received HIFU monotherapy, while 175

*GI: incontinence grade I, i.e. loss of urine under heavy exercise requiring 0–1 pad/day; GII, incontinence grade II, i.e. loss of urine under light exercise requiring >1 pad/day; GIII, incontinence grade III, i.e. loss of urine under any exercise requiring >2 pads/day.
CA, Postoperative catheter duration; ED, erectile dysfunction; F, Foley catheter; FIS, fistula;, INC, incontinence; NR, not reported; PR, postoperative retention; SP, suprapubic catheter; S&S, stricture and stenosis; TURP, transurethral resection of the prostate; UTI, urinary tract infection.

were treated with combination therapy. The mean resection weight was 15.7 g (2–110 g) and median weight 12.5 g. In 51.6% of the patients, carcinoma was found in the resection material. The mean follow-up time for the monotherapy group was 18.7 ± 12.1 months and for the combination therapy group was 10.9 ± 6.2 months. The histologic results in both groups were similar after treatment, with negative biopsies in 87.7% versus 81.6%. The median PSA nadir was 0.0 ng/mL in both groups. The monotherapy group required a suprapubic catheter for 40 days, while in the combination group it was removed after 7 days.

The rate of adverse events among patients with primary therapy is low (Table 115.2): grade I stress incontinence was observed in 4–6% of patients, grade II in 0–2%, and secondary intermediate infravesical obstruction in 5–10%. Severe incontinence (grade III) and urethrorectal fistulas are rare (<1%). Preservation of erectile function is directly dependent on the position of the primary lesion in relation to the neurovascular bundle. Sparing the contralateral side for neurovascular preservation can improve potency, however this results in a higher retreatment rate [51–54].

Radical prostatectomy after HIFU

Between 1996 and 2000 we performed seven prostatectomies after HIFU. This was due to incomplete HIFU treatments of larger prostates. At this time we did not perform combination therapy with TURP before HIFU. HIFU treatment had caused severe fibrotic adhesions between the rectum and Denovilliers' fascia which posed surgical challenges. In the area of the bladder outlet no changes were observed neither in the lateral nor in the ventral portion of the prostate. While radical prostatectomy after HIFU is more demanding, in our experience it was not associated with higher morbidity compared to a standard prostatectomy.

HIFU after brachytherapy

Limited experience exists of HIFU following brachytherapy. It appears that this approach is not associated with a significant increase in complications compared with primary HIFU. However, it seems advisable to monitor the position of the seeds precisely before HIFU (MR). Seeds should not be outside the prostate capsule and especially not between the rectum and prostate where they will interfere with the direct entry path of the ultrasound.

HIFU after radical prostatectomy

Local recurrence after radical prostatectomy occurs in about 30% of cases. HIFU offers a treatment option when local recurrence can be identified through TRUS and the area is accessible by the therapeutic transducer (depth 25 mm). After treatment with HIFU, the treated areas showed negative biopsies in 77%. The PSA nadir averaged 0.2 ng/mL and 66% of the patients achieved nadir values of 0.5 ng/mL. During follow-up of 5 years, 91% of patients showed no biochemical progress [55, 56].

HIFU after radiation therapy

HIFU has been performed as salvage therapy following external radiotherapy failures. Gelet *et al.* reported results of 71 patients [57]. All patients were diagnosed with a biochemical recurrence and local disease was confirmed by biopsies. In one-third of patients androgen deprivation was employed either as a measure for auxiliary radiotherapy or for early biochemical relapse, prior to HIFU treatment. During follow-up after HIFU for a median of 14.8 months (range 6–86), 80% of treated patients showed negative biopsies . The median PSA nadir was 0.2 ng/mL. Despite these satisfactory results, 40 patients (56.3%) required additional auxiliary treatment. The need for adjuvant therapy resulted from an isolated increase in PSA (36.6%) or the detection of a histologically proven recurrence. In this group, four patients died of metastatic prostate cancer. The high rate of patients with rising PSA despite negative histologic findings may indicate that in this population extraprostatic manifestation can be assumed. In patients with HIFU as salvage therapy after external radiotherapy a significantly higher rate of side effects is observed, compared with patients who undergo primary HIFU therapy. Nevertheless, there is a favorable risk–benefit ratio after HIFU treatment as compared to the alternatives [58].

Palliative therapy

Preliminary results for the palliative treatment of advanced prostate cancer with HIFU are promising in terms of reduction in local morbidity (rectal compression, infravesical obstruction, hydronephrosis, hematuria, pelvic pain syndromes). Unpublished data in several large patient groups (n > 70) with T3 and hormone refractory prostate cancer (HRPC) show a post-HIFU PSA velocity of 0.19 ng/mL/year with follow-up of 10 years (without additional hormone ablation). Local tumor ablation with HIFU also resulted in a PSA reduction in 80% of the HRPC cases. There was also evidence of a synergistic effect in hormone ablative therapies, with delays seen in the onset of hormone resistance [55, 59].

Predicting outcome after high-intensity focused ultrasound

The prediction of treatment outcome in patients treated with radical prostatectomy is based on pathologic features such as tumor grade, stage, margin status. Due to the absence of histologic specimens following HIFU, it is necessary to consider other predictors of treatment outcome. PSA nadir as a predictor of clinical failure following HIFU has been shown to be a strong predictor of treatment failure [60]. In a 6-month study involving 115 patients, failure rates following HIFU were 11% (four of 36) in patients with a PSA nadir of 0.0–0.2 ng/mL compared with 46% (17 of 37) in patients with a PSA nadir of 0.21–1 ng/mL and 48% (20 of 42) in patients with a PSA nadir of greater than 1.0 ng/mL. In addition, the PSA nadir was strongly associated with both preoperative PSA level and residual prostate volume. The validity of PSA nadir as a predictor of outcome over a longer follow-up has been reported by Ganzer *et al*. [61]. The median follow-up was 4.9 (3–8.6) years and patients were divided into three PSA nadir subgroups (≤0.2 ng/mL, 0.21–1 ng/mL, and > 1 ng/mL). Treatment failure was defined according to American Society for Therapeutic Radiology and Oncology (ASTRO) criteria. It was shown that the PSA nadir after HIFU correlated highly significantly with treatment failure and disease-free survival rate. Treatment failure rates during follow-up were 4.5%, 30.4%, and 100%, respectively, for the three PSA nadir groups ($P < 0.001$). The actuarial disease-free survival rates at 5 years were 95%, 55%, and 0%, respectively, for the three groups ($P < .001$). These findings suggest that outcome is improved if a PSA nadir of ≤0.2 ng/mL is reached.

Immunologic response after high-intensity focused ultrasound

Recent progress has been made in developing an effective immune strategy for treating prostate cancer. A number of immunotherapy regimens are being studied, including immunomodulatory cytokines/

effectors, peptide and cellular immunization, viral vaccines, dendritic cell vaccines, and antibody therapies. Immunomodulatory agents, such as granulocyte–macrophage colony-stimulating factor (GM-CSF), Flt3 ligand, and interleukin (IL)-2, have been used to stimulate the immune system to generate an antitumor response against prostate cancer. A number of vaccine-based approaches have also been studied based on prostate- or tumor-specific antigens, including PSA, prostatic acid phosphatase, prostate-specific membrane antigen, and prostate stem cell antigen. GVAX® is a cellular vaccine that uses exogenous tumor cells engineered to secrete GM-CSF, which is thought to increase dendritic cell presentation of antigens to the immune system. However, encouraging early preclinical results have not been extended into the clinical setting.

Several studies have looked at the potential of HIFU to initiate an immune response. Wu *et al*. examined the effect of HIFU on systemic antitumor immunity, particularly T-lymphocyte-mediated immunity in cancer patients [62]. A total of 16 patients with solid malignancies were treated with HIFU, including patients with osteosarcoma, hepatocellular carcinoma, and renal cell carcinoma. The results showed a significant increase in the population of CD4(+) lymphocytes and the ratio of CD4(+)/CD8(+) in the circulation of cancer patients after HIFU treatment. The authors concluded that HIFU could enhance a systemic antitumor cellular immunity in addition to local tumor destruction in patients with solid malignancies.

The same group investigated whether the tumor antigens expressed on breast cancer cells could be preserved after HIFU treatment [63]. Primary lesions in 23 patients with biopsy-proven breast cancer were treated with HIFU, and these were then submitted to modified radical mastectomy. Breast cancer specimens were stained for a variety of cellular molecules, including tumor antigens and heat-shock protein 70 (HSP-70). A number of tumor antigens were identified and these may provide a potential antigen source to stimulate antitumor immune response.

It has been suggested that endogenous signals from HIFU-damaged tumor cells may trigger the activation of dendritic cells and that this may play a critical role in an HIFU-elicited antitumor immune response [64]. A mouse model bearing MC-38 colon adenocarcinoma tumors was treated with thermal and mechanical HIFU exposure settings in order to independently observe HIFU-induced effects on the host's immunologic response. Results showed that HIFU elicited a systemic antitumor immune response that was closely related to dendritic cell activation. Dendritic cell activation was more pronounced when tumor cells were mechanically lysed by focused ultrasound treatment.

The status of tumor-infiltrating lymphocytes (TILs) after HIFU ablation of human breast cancer has been investigated [65]. Results show that TILs infiltrated along the margins of the ablated region in all HIFU-treated neoplasms, and the numbers of tumor-infiltrating CD3, CD4, CD8, CD4/CD8 B lymphocytes, and natural killer cells was increased significantly with HIFU treatment. The number of FasL(+), granzyme(+), and perforin(+) TILs was significantly greater in the HIFU group than in the control group.

Focal therapy

Future treatment options for prostate cancer that are being considered include the development of more focused therapy and immunotherapy. The goal of more focused therapy for prostate cancer is to selectively ablate known disease while reducing associated morbidity. In the case of unilateral disease and where potency is an important issue for the patient, it would be advantageous to exclude the contralateral lobe/capsule and neurovascular bundle. Ideally, this would be achieved by excluding 5 mm of tissue on the contralateral lobe and treating only 90% of the prostate. This approach may be appropriate in young patients, with small, low-grade, unilateral tumors. Patients requesting this approach would need to be advised of the risk of tumor recurrence in the untreated area and the requirement for good compliance with follow-up. There are several critical issues that need to be addressed regarding focal therapy of prostate cancer. The first is the accurate identification and localization of the so-called "index lesion" within the prostate on which to focus therapy. There are also issues relating to the effectiveness of focal treatments and how patients should be monitored following treatment, whether this is with PSA, biopsy, or perhaps imaging in the future.

Transperineal three-dimensional (3D) mapping biopsies are considered by some to be more accurate than TRUS-guided biopsies in excluding patients with clinically significant disease outside the areas to be ablated. Transperineal 3D mapping biopsies revealed that of 110 patients shown to have unilateral disease on standard TRUS biopsy, 60 (55%) had, in fact, bilateral cancer [66]. The Gleason score on 3D biopsy was also higher in 25 patients (23%) over the original findings, indicating that transperineal prostate mapping may provide better pathologic assessment of the entire prostate gland. The localization of tumor within the gland both before and after treatment is another important issue. The application and continued development of a variety of imaging techniques are likely to provide improvements in the visualization and assessment of HIFU lesions in the near future. With regard to localizing disease, variable sensitivity of MRI has been reported [67]. Functional imaging

techniques, such as dynamic contrast-enhanced (DCE) MRI, diffusion-weighted imaging (DWI), and magnetic resonance spectroscopic imaging (MRSI), have been evaluated in an attempt to improve the detection and localization of prostate cancer [68–70]. Results suggest that vascular information from DCE-MRI or DWI-MRI combined with metabolic data from MRSI have extremely good potential for improving the accuracy of defining and staging prostate cancer.

In terms of assessing the efficacy of HIFU treatment, MRI is the gold-standard technique and the extent of necrosis can be clearly visualized on gadolinium-enhanced T1-weighted images [42, 71]. MRE may also provide a means of assessing the effects of thermal tissue ablation by measuring the mechanical properties of the lesion [72]. HIFU-induced lesions are visible using standard ultrasound [17], although there are limitations to the accuracy of this approach. Other ultrasound-based techniques that may prove useful for assessing the extent of HIFU-induced lesions include contrast-enhanced power Doppler [18] and other techniques that characterize the acoustic properties of tissues.

Focal therapy has been compared with whole-gland ablation in a series of 70 patients [73]. Of the 29 patients with unilateral disease, focal therapy involved ablation of the total peripheral zone and half of the transitional zone, and resulted in a 77% negative biopsy rate at 12 months. Of the remaining 41 patients with bilateral disease, whole-gland ablation resulted in an 84% negative biopsy rate at 12 months. Two-year biochemical recurrence-free survival rates were 91% and 50% for low- and intermediate-risk groups undergoing whole gland ablation, respectively, compared with 83% and 54%, respectively, for the focal therapy equivalents. Morbidity with the two forms of HIFU was comparable.

Conclusions

HIFU is an evolving and effective treatment for prostate cancer [74], with a wide range of indications in all tumor stages. HIFU is indicated for localized prostate cancer (stage T1–T2 N0M0, Gleason score 1–3) and partial therapy is being explored for low volume, low Gleason score tumors. Furthermore, it has been successfully used as salvage therapy in recurrent prostate cancer after radical prostatectomy, radiotherapy, and hormone ablation, and as a debulking approach in advanced prostate cancer. While other nonsurgical treatment options for localized prostate cancer (e.g. cryotherapy or brachytherapy) cannot generally be repeated in cases of local recurrence, HIFU can be repeated. Postprocedural morbidity is low; however, clinically significant complications can occur, including incontinence and erectile dysfunction. However, specific measures can be taken to avoid the latter. HIFU is an effective treatment for patients with localized prostate cancer and can also be considered for patients with metastatic disease. Promising advances in HIFU include new treatment strategies for specific patient groups.

CHAPTER 116
Cryotherapy of the Prostate

Matvey Tsivian & Thomas J. Polascik
Division of Urology, Department of Surgery, Duke University Medical Center, Durham, NC, USA

Introduction

Cryosurgery has been used in cancer treatment since the 1850s when rudimental frozen salt solutions were applied to advanced cancers with reported reduction in tumor size [1]. Since then, technologic advances have allowed for the evolution of cryosurgery into its current form whereby it represents a recognized option for the treatment of prostate, kidney, and other cancers. In this chapter we discuss the principles of cryobiology, current indications for cryotherapy of the prostate, and procedure details, and summarize the outcomes as reported in the literature.

Cryobiology: general principles

Cryogenic injury

It is common knowledge that freezing can cause tissue destruction, e.g. frostbite. The mechanisms underlying this effect can be summarized in two categories: direct cellular injury and vascular cryogenic injury [2].

Direct cellular injury has been extensively studied in cell culture models and is based on water biophysics and ice formation within the frozen tissue. Two separate mechanisms of ice formation have been described [2, 3]. Extracellular ice formation occurs as the freezing propagates through the tissue and is responsible for an increase of solute concentration in the extracellular space, causing cell dehydration [4] which disrupts enzymatic processes and alters cell membrane properties (solution-effect injury) [5]. The second direct injury mechanism is represented by intracellular ice formation that occurs at high freezing rates (rapid freezing) and allows for water entrapment within the cell before dehydration has occurred. Intracellular ice formation alters cell physiology by disrupting membranes and contributes to cell death by direct cryogenic injury. Increasing the duration of exposure to lethal temperatures (–40°C) enhances the efficacy of tumor cell destruction [6] as very little water remains unfrozen at temperatures below –40°C [7]. During thawing additional mechanisms of damage contribute to tissue destruction. Recrystallization occurs when temperature rise above –40°C. In the recrystallization process, smaller ice crystals fuse to form larger structures that inflict additional damage on cell structures. Moreover, as extracellular ice crystals melt, a hypotonic extracellular environment is created and water is pushed into the cells and may inflict further membrane damage by volume overload [3]. It has been suggested that passive thawing may be more efficient in prostate cancer destruction [6].

The second category of cryogenic injury is the vascular mechanism (Figure 116.1). This type of cryogenic injury occurs preferentially in the microcirculation where endothelial cell damage and sloughing along with vessel wall distention, increased vessel permeability, stasis, and thrombosis determine ischemia and inflammation, and contribute to tissue necrosis [2]. Additionally, thawing and reperfusion injury mediated by free radicals augment the endothelial damage and enhance the inflammatory process and enzymatic degradation of cell debris.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

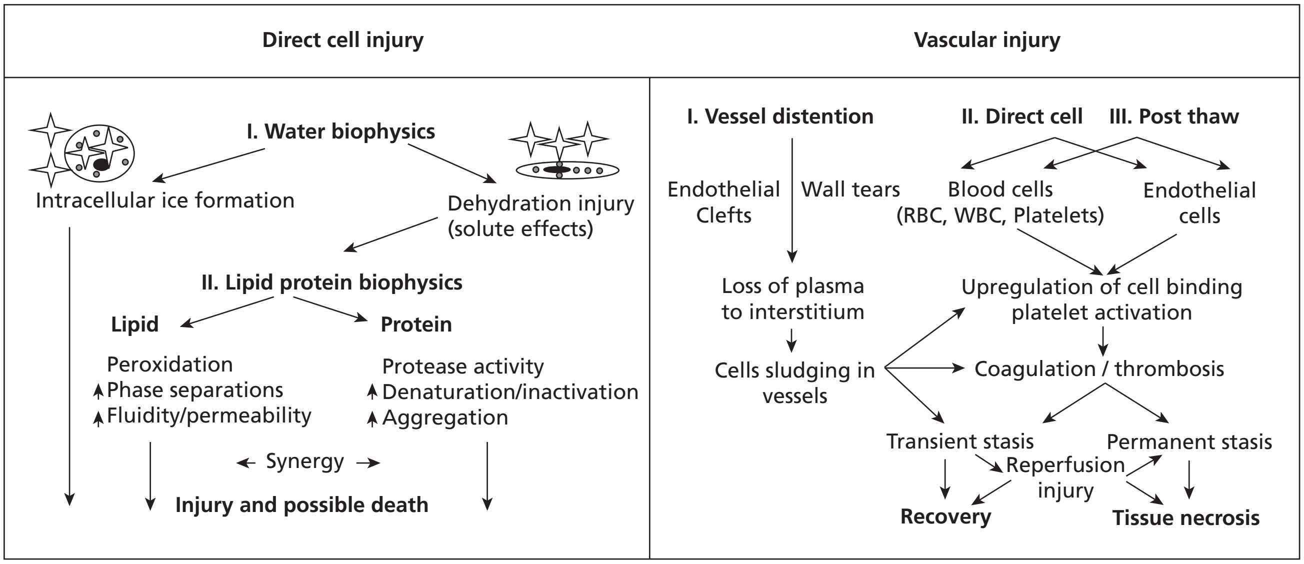

Figure 116.1 Direct and vascular cryogenic injury. RBC, red blood cell; WBC, white blood cell (adapted from Hoffmann and Bischof [2], with permission).

Cryogenic injury progresses as the temperature drops and is a time-dependent process. While cell dehydration occurs at temperatures between 0°C and –20°C, this effect alone may induce only a reversible cellular injury. Intracellular ice begins to form at temperatures below –15–20°C and at –40°C induces lethal effects on the cell [8]. Therefore, tissue that reaches –40°C and below will usually be effectively destroyed (lethal or killing zone), but surrounding tissue that does not reach this threshold is affected by sublethal, reversible cryogenic injury (Figure 116.2). At the edges of the lethal zone, apoptosis represents an additional mechanism of cell death. Apoptosis seems to peak several hours after the cryogenic stimulus has been removed [9].

Understanding the mechanisms of cryogenic injury is essential to be able to propose potential cryosensitizers, i.e. agents potentially able to increase the efficacy of cryotherapy or target cell destruction with more precision, limiting it to cancer tissue while sparing surrounding structures.

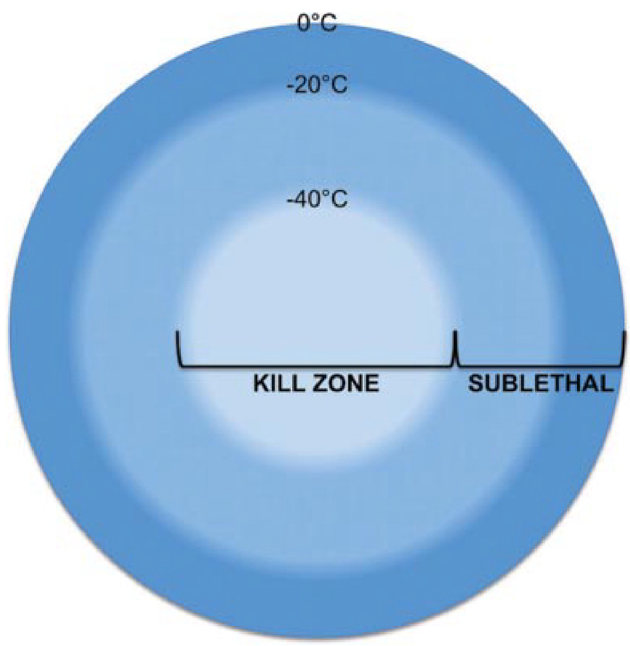

Figure 116.2 Lethal and sublethal zones during cryoinjury. The sublethal zone represents a spectrum whereby cryoinjury may be reversible: the colder the temperature achieved within this temperature gradient, the less likely the cancer cell can survive.

Cryoimmunology

In contrast to conventional surgical extirpation whereby tissue is removed from the organism, cryotherapy-induced cellular destruction releases antigenic structures that are processed by immunocompetent cells and may elicit an immune response. However, the entity of such a response is debated. Reported data are controversial, suggesting that the elicited immune response may be either immune-stimulating [10–13] (promoting the destruction of residual local or metastatic deposits) or immunosuppressive [14, 15] (inducing tolerance to the presented antigens). The nature of the immune reaction is likely dependent upon local factors such as cytokine response induced by cryoablation, the type of antigen-presenting cells (dendritic cells vs macrophages), and the antigen in a form that may be presented by the competent cells [16].

While the potential of evoking a specific immune anticancer response is intriguing, preclinical data are controversial and further research is needed to be able to exploit this aspect of cryoablation to potentially increase the efficacy of tumor destruction.

Indications for Cryotherapy of the Prostate

Primary cryoablation

Primary cryoablation is considered an option for the treatment of localized prostate cancer. The American Urological Association's (AUA) Best Practice Statement from 2008 considered cryosurgery to be an option for patients who either do not desire or are not good candidates for conventional radical surgery [17]. The European guidelines state that cryosurgery is an experimental therapeutic option for clinically localized prostate cancer [18].

The European Association of Urology (EAU) guidelines define as ideal candidates patients with organ-confined prostate cancer, or having minimal extension beyond the prostate, prostate volume 40 mL or smaller, prostate-specific antigen (PSA) less than 20 ng/mL, and Gleason score less than 7, although intermediate-risk patients may represent potential candidates as well [18]. Large prostates can benefit from neoadjuvant hormonal therapy to reduce the size of the gland, although the effect of this approach on subsequent outcomes remains to be determined. The Best Practice Statement from the AUA [17] indicates cryosurgery as an option for low-, intermediate-, and high-risk clinically localized prostate cancer, setting no apparent limits to PSA values, clinical stage or biopsy Gleason score. However, this document does not specifically address the suitability for cryosurgery of high-risk patients who may require multimodality treatment.

Other than disease characteristics (PSA, Gleason score, clinical stage), additional factors should be considered when evaluating potential candidates for primary cryoablation. History of transurethral resection of the prostate represents a relative contraindication for cryosurgery. Large defects in the prostatic fossa may reduce the effectiveness of the protective urethral warmer and thereby increase the chance of urethral mucosa sloughing. Similarly, the presence of major rectal pathology may constitute a relative contraindication for cryoablation. In addition, since impotence is a common outcome after whole-gland cryosurgery, potent patients concerned with erectile function should be preoperatively counseled about realistic expectations with this approach.

The apparent lack of strong recommendations in the guidelines derives from a paucity of clinical data and long-term outcomes of primary cryosurgery. Therefore, more research is needed before solid recommendations can be made. Nevertheless, it seems that the experts agree that suitable candidates are those who fall into the low–intermediate risk categories. It is reasonable to presume that patients with low-risk disease are likely to have better outcomes, similarly to conventional surgical treatment.

In summary, primary cryoablation represents an alternative minimally invasive treatment option for localized prostate cancer. Patients with low- and intermediate-risk disease who are unsuitable for conventional radical surgical treatment likely represent the ideal candidates for cryosurgery. Cryosurgery may also be considered as primary treatment in appropriately selected high-risk prostate cancer patients as an alternative to conventional treatment.

Salvage cryoablation

Salvage cryosurgery after radiation therapy failure has been proposed as an alternative to salvage radical prostatectomy with the potential of less morbidity. Salvage cryoablation has been reported after interstitial therapy as well [19]. Few data are available in the literature with regards to the outcomes of salvage cryosurgery. Potential candidates for salvage cryoablation are those with biopsy-proven locally recurrent prostate cancer after primary radiation or ablative therapy in the absence of metastatic disease.

Candidates for salvage cryoablation after radiation failure include patients with biochemical failure post primary radiation therapy according to current definitions of biochemical failure (ASTRO, Phoenix) and prostate biopsy demonstrating locally recurrent disease with no clinical or radiologic evidence of distant metastases. Biopsies of the seminal vesicles in this setting are recommended, as seminal vesicle involvement may preclude a successful salvage cryoablation with curative intent. Lymph node sampling may be considered as part of the evaluation in high-risk patients.

Factors associated with the success of salvage cryoablation include: low PSA values (<4 ng/mL) at the time of salvage cryoablation [20, 21] and at the time of primary therapy [22]; PSA nadir after primary therapy [22]; PSA doubling time [21]; and low Gleason grade of the recurrent disease [20].

Based on these data, the optimal candidate for salvage cryosurgery is a patient with biopsy-proven locally recurrent prostate cancer with no evidence of distant spread or seminal vesicle involvement, a PSA less than 4 ng/mL, PSA doubling time greater than 16 months, with favorable primary disease characteristics (low PSA, low Gleason score).

Cryoablation procedure

As technology has improved over the years, we discuss only the current third-generation technology, leaving the description of previous techniques (first and second generations) to historical reference.

Third-generation cryotechnology is based on dual-gas systems exploiting the Joule–Thompson principle of gas expansion to provide heat subtraction and delivery through small caliber cryoprobes. The same effect is used in home appliances, such as air conditioning systems and refrigerators. Briefly, these systems use pressurized argon and helium gases delivered to the cryoprobe in a closed circuit. When argon gas is allowed to expand through a pinhole opening at the tip of the cryoprobe, the gas changes its internal energy state as the pressure drops and the process consumes energy thereby reducing the temperature. The inverse process happens during thawing whereby helium is expanded in the cryoprobe, thus releasing energy and heating the probe. The opposite effects achieved with the two gases derive from different molecular properties (internal energy) of argon and helium gases, based on attractive and repulsive forces of gas molecules. The latest technology introduced an argon-only system whereby both freezing and thawing phases are achieved by altering the physical properties of argon, thus simplifying the technologic complexity of cryoablation and obviating the need for an additional gas.

The cryoablation suite consists of a console that monitors and controls the procedure, argon (and sometimes helium) pressurized gas tanks, a urethral warming device, and peripherals (transrectal stepper-mounted ultrasound, cryoprobes, and thermocouples). The system's user interface integrates ultrasonographic imaging that guides cryoprobe positioning and monitors the formation of the ice ball, receiving input from the urethral warmer and the temperature probes.

Different numbers, positions and configurations of probes allow for sculpturing of the ice ball with precision. Cryoprobes and thermocouples are positioned transperineally through a brachytherapy-like template (Figures 116.3 and 116.4). Currently, thin and ultrathin (17G, 1.5 mm) cryoprobes are available. Ice-ball formation is monitored both by temperature probe readings and by realtime ultrasound.

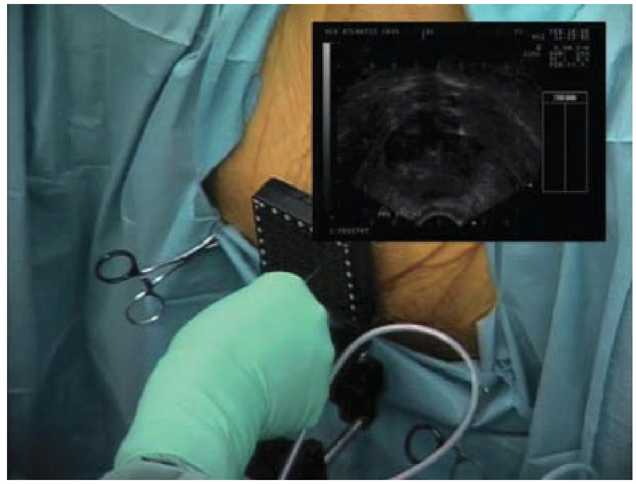

Figure 116.3 Transperineal cryoprobe positioning using a brachytherapy-like template under ultrasound guidance. Stepper-mounted ultrasound probe with template and cryoprobes.

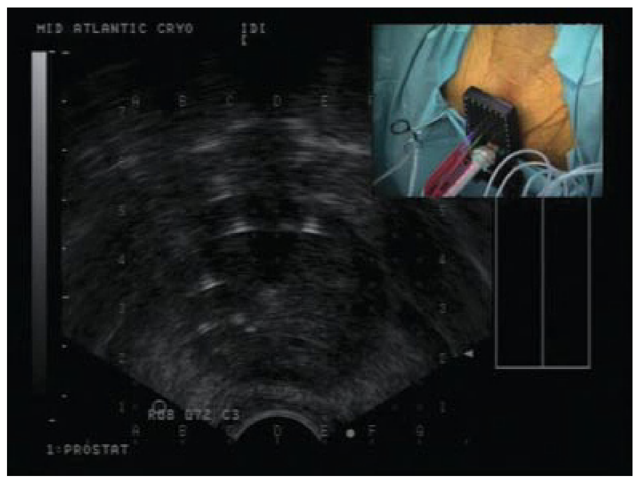

Figure 116.4 Cryoprobes positioned with ultrasound guidance.

Cryoablation is typically an outpatient procedure and can be performed under general, spinal or locoregional anesthesia. With the patient in lithotomy position, probes are positioned using the grid under the guidance of transrectal ultrasound. Thermocouples are typically positioned adjacent to the neurovascular bundles, sphincter, and Denonvilliers' fascia to assist with ice-ball monitoring. After probe positioning, flexible cystoscopy is used to verify that the probes have not penetrated the urethra or bladder. The urethral warming device is then introduced over a super-stiff guidewire. Although some surgeons place a suprapubic tube to provide bladder drainage in the postoperative period, a urethral catheter can alternatively be utilized at the end of cryoablation, replacing the urethral warming device. Freezing proceeds in an automated manner, using dual freeze–thaw cycles, monitored by ultrasound and thermocouple readings.

Cryoablation results in acute swelling of the prostate that typically resolves in 1–2 weeks, during which time a urethral catheter (or a suprapubic tube) provides bladder drainage. After a successful voiding trial, the catheter can be removed. We recommend assessing

voiding ability within 1 week postoperatively as in our experience most patients are able to spontaneously void by that time.

Outcomes

Complications of primary cryoablation

Despite its minimally invasive nature, primary cryoablation of the prostate is not devoid of complications. Minor self-limiting complications that are often overlooked in the scientific literature include transient scrotal or penile swelling and penile paraesthesia, which can be reported in up to 10% of patients [23, 24]. These typically occur within 2–3 weeks post procedure and resolve in 2–6 months. Table 116.1 reports a literature summary of complications after primary cryoablation.

Urethral mucosal sloughing is rare and in most series is reported to occur in less than 5% of patients. The incidence of rectourethral fistula today is also low (0–2.4%). Urinary incontinence requiring pads has been reported to occur in less than 10% of patients and is typically transient. The incidence and presentation of incontinence has been reported using various definitions, with most studies not distinguishing between stress, urge, and mixed incontinence, making it challenging to derive precise conclusions. The incidence of urinary retention has varied widely across the literature and requires further evaluation as technical differences may have accounted for this discrepancy between studies. However, the majority of urinary retention events are transitory and resolve within 2–4 months. The more recent series suggest urinary retention may occur in less than 5% of cases [25, 26].

A recent report based on the CaPSURE database analyzed the incidence of urethral stricture after primary therapy for prostate cancer [27]. The overall incidence of stricture after primary cryosurgery was 2.5%. At 1, 2, and 4 years, 96%, 95%, and 87%, respectively, of cryotherapy patients were stricture free, respectively. These data compare favorably to other treatment options: incidence of stricture formation 1.1% for watchful waiting, 2% for androgen-deprivation therapy 2%, and 8.4% for radical prostatectomy [27].

Currently, the available data are limited both due to many of the reported series being updates of previous studies and because data collection has not been standardized, thus precluding a detailed and accurate description of complications after cryoablation. Researchers should strive to better collect follow-up information to delineate accurately the complications profile and determine risk factors for these adverse events.

Complications of salvage cryoablation

A summary of complications after salvage cryoablation is outlined in Table 116.2. Overall, the complication profile appears similar to that for primary cryoablation (see Table 116.1), with the exception of higher incontinence and pelvic pain rates. Overall, salvage cryoablation offers a complication profile that compares well with other salvage techniques. A recent review of the literature concluded that salvage cryoablation offers a viable alternative to the technically challenging salvage

Table 116.2 Complication rates after salvage cryoablation using third-generation cryotechnology.

radical prostatectomy, and thus is recognized as an established option in radiorecurrent prostate cancer [28].

Functional outcomes: continence and potency

Continence and potency outcomes are outlined in Tables 116.1 and 116.2. Erectile dysfunction is highly prevalent after whole-gland primary and salvage cryoablation. Therefore, the desire to preserve potency should be carefully considered when discussing whole gland cryoablation as a management option for localized prostate cancer.

Continence is preserved after salvage cryoablation in the vast majority of patients. Most series report a less than 10% incidence of urinary incontinence (Table 116.2). A recent analysis of urinary function after primary and salvage cryoablation using validated instruments has shown excellent functional outcomes [29]. In this study, salvage cryoablation demonstrated inferior urinary function results compared to the primary setting. However, the authors showed that International Prostate Symptom Score (IPSS) and bother index (BI) score worsened immediately after the procedure but recovered steadily thereafter, and the improvement (compared to preoperative values) persisted at 12 months post procedure. Another group reported no significant changes in AUS symptom score (AUASS) after primary cryoablation [30]. These studies suggest that cryoablation does not negatively impact urinary function. On the contrary, urinary function may be improved after cryoablation and this effect can be appreciated 6 months postoperatively.

Prostate cryoablation has acceptable functional outcomes both in the primary and salvage setting. In the salvage setting, cryoablation compares well with salvage surgery and other treatment modalities for recurrent prostate cancer. Salvage cryotherapy is less technically challenging compared to surgery, offers acceptable oncologic and functional outcomes whereas surgery for radio-recurrent prostate cancer remains a highly morbid approach.

An analysis of quality-of-life outcomes after primary and salvage cryoablation has shown similar results in terms of physical symptoms, sexuality, and bowel symptoms evaluated using standardized questionnaires [31]. This study has also demonstrated sexual dysfunction and urinary symptoms to be the most prominent and bothersome symptoms. Severe erectile dysfunction was reported in 86% and 90% of primary and salvage cryoablation patients. These quality-of-life outcomes are comparable to those reported in radiotherapy series [32, 33]. Finally, a recent randomized trial comparing quality-of-life outcomes for primary cryoablation versus external beam radiation concluded that there is no long-term advantage for either treatment, with the exception of sexual function outcomes which favor radiation therapy [34].

Cancer control outcomes

Tables 116.3 and 116.4 outline the reported cancer control outcomes of primary and salvage cryoablation, respectively. There is sensible variability in the definition of biochemical recurrence in the literature, from PSA cutoff values (0.4, 0.5, 1.0 ng/mL) to American Society for Therapeutic Radiology and Oncology (ASTRO; three consecutive PSA rises [35]) and Phoenix (nadir +2 [36]) criteria. Biochemical failure criteria used in conventional radical surgery are not suitable for cryoablation, as with the use of urethral warming devices a portion of prostatic tissue is variably spared and undetectable PSA values are rarely sustained after cryoablation. Currently, there is no consensus on the definition of biochemical failure after cryoablation and the use of diverse definitions in the literature makes for a challenging accurate comparison of the reported outcomes.

Table 116.3 Oncologic outcomes of primary cryoablation.

Pisters *et al.* [56]*	279	ASTRO	–	–	59	–

*Not pure third-generation technology.

Despite the variations in the definitions of biochemical failure, available data suggest acceptable oncologic outcomes with regards to biochemical disease-free survival of up to 5 years. Data are yet to mature on metastatic progression and cancer-specific survival along with long-term (10–15 years) local cancer control. Most available series are either single institution or single surgeon, or report pooled data for several surgeons. The only two randomized clinical trials of primary cryoablation compared to external beam radiation provide discordant conclusions [37, 38]. While Chin *et al*. found significantly poorer oncologic outcomes for cryoablation [37], Donnelly *et al*. in a larger clinical trial suggested that the two approaches provide comparable biochemical disease-free survival [38]. Of note, the former trial enrolled exclusively patients with locally advanced disease (clinical stage T2c–T3b), whereas the latter explicitly excluded patients with bulky T3 prostate cancer. Moreover, the strength of the results of Chin *et al*.'s study is limited by its sample size [37].

In summary, from the available data, it appears that primary cryoablation offers overall solid cancer control outcomes. In the salvage setting, the outcomes are competitive with salvage prostatectomy and, combined with a favorable morbidity profile, suggest that cryoablation is a first-line treatment option for radiorecurrent prostate cancer in appropriately selected patients. Further research is required to formulate a solid definition of biochemical recurrence considering the unique aspects of cryoablation. Definitions borrowed from radiotherapy, albeit useful in the absence of alternatives, cannot be fully adapted to the cryoablation field. As experience with current cryotherapy technology grows, we are likely to see long-term results in the near future.

Future directions: Focal therapy

The utilization of probe-based ablation has introduced the possibility of treating less than the whole gland. The concept of focal therapy, i.e. treating known foci of cancer while sparing unaffected portions of the gland, thereby potentially preserving a better quality of life, has recently gained interest [39–41]. Hemiablation of the prostate in patients with unilateral or unifocal prostate

cancer potentially spares at least one neurovascular bundle and therefore has the ability to achieve much better erectile function outcomes compared to whole-gland cryoablation. A series of 60 patients treated with focal cryoablation reported 72% potency rates after the procedure [42]. Another group showed a 88.9% preservation of potency after focal cryotherapy [43]. Biochemical disease-free survival rates range between 84% and 96% after 28–70 months of follow-up [43–46]. The preliminary results of focal cryoablation indicate a low morbidity profile and acceptable cancer control [45]. However, no randomized trials are available to evaluate the focal cryoablation approach under strict criteria.

Appropriate candidate selection represents probably the main obstacle to a widespread diffusion of focal therapy as a concept. Currently, available imaging tools are insufficient to reliably and accurately detect and map cancerous foci within the prostate [47]. Extensive biopsy schemes are, at this moment, the best means to accurately depict the extent of the gland's involvement by cancer and thereby select appropriate candidates for focal therapy [48]. Novel imaging techniques are being developed and show promising results with a potential role as selection tools in the setting of focal therapy [49, 50].

Focal therapy represents an attractive concept and initial results are encouraging. The interest in this approach is evident but the results are still immature. No consensus exists on methods or criteria of patient selection. The urologic community is awaiting more data to investigate the place of focal therapy among the already established management options for localized prostate cancer.

CHAPTER 117

Contrast-Enhanced Ultrasound in Urology

Bastiaan Brand, Jean de la Rosette & Hessel Wijkstra
Department of Urology, AMC University Hospital, Amsterdam, Noord-Holland, The Netherlands

Introduction

Imaging in endourology is mainly comprised of gray-scale ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and skeletal scintigraphy. All of these modalities have their own place in urology, and in this chapter we focus on contrast-enhanced ultrasound (CEUS) as it compares with MRI and CT imaging.

CT scans are commonly used in the diagnosis, staging, and follow-up of urologic malignancies. In the diagnosis of kidney tumors, ultrasound is mainly used for a first screening and in most cases, CT is utilized to make the final diagnosis. MRI is commonly used to evaluate adrenal tumors and cystic lesions in the kidney, and to stage renal cell and prostate carcinoma. For some urologic indications, MRI is used when CT is contraindicated.

The downside of CT and MRI is that they are relatively expensive and less available. Furthermore, CT and MRI contrast agents can have severe side effects [1–3]. CT contrast agents are iodine based and in patients with renal insufficiency these agents can worsen the existing renal function. CT is also associated with significant radiation exposure. Although MRI does not exposure patients to ionizing radiation, MRI contrast agents are gadolinium based and in patients with severe renal failure these agents can cause nephrogenic systemic fibrosis (NFS) [2].

Ultrasound is a safe method to investigate the kidney, bladder, prostate, scrotum, and penis. It has high resolution, offers realtime imaging, is easily available, can be used at the bedside, and is a relatively inexpensive imaging technique.

For diagnosing scrotal abnormalities, ultrasound is the investigation of choice. When used appropriately, ultrasound can distinguish between the most common scrotal abnormalities [4, 5] Doppler investigation allows direct evaluation of testicular perfusion, making it ideal to further distinguish between scrotal abnormalities. However, the diagnostic accuracy of gray-scale and Doppler ultrasound for malignant processes of the kidney, bladder, and prostate is low. For the bladder and kidney, it is mainly used as a screening tool, and for prostate cancer its main role is to guide systematic biopsies.

Malignancies are associated with neovascularization and therefore changes in perfusion [6, 7]. If these changes can be visualized, this may increase the sensitivity and specificity of tumor detection and the accuracy of staging. Suitable techniques for perfusion imaging are dynamic or contrast MRI, contrast CT, and CEUS.

CEUS was first described in 1968 during the imaging of the aortic root [8]. After an injection of saline, it was noted that the small air bubbles present in the saline enhanced the ultrasound signal significantly. Thereafter, attempts to use free air bubbles as an ultrasound contrast agent have been conducted. However, the main problem was the short lifetime of these bubbles. During the last decade, new ultrasound contrast agents have been developed that consist of small (<8 μm) encapsulated gas-filled microbubbles. Due to the shell around the gas bubbles, their lifetime is substantially increased. Currently available contrast agents have a lifetime of

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

several minutes, and thus with a simple intravenous injection the contrast will become visible in urologic organs. The first application of CEUS was in cardiology for the visualization of myocardial perfusion, and currently its usage is extended to imaging of the liver, breast, kidney, and prostate [9–14].

When microbubbles are exposed to sound waves they are compressed and subsequently expanded as a result of the changing ultrasound pressure. With low-energy ultrasound waves, the bubbles expand linearly, and behave like additional bloodstream reflectors, resulting in increased reflected ultrasound energy. This mode is especially useful in Doppler ultrasound imaging [15].

With medium energy waves the bubbles expand nonlinear which results in reflected signals that not only encompasses the transmitted ultrasound frequency, but also additional harmonics. Currently available contrast-specific imaging techniques utilize these harmonics to distinguish between the reflections of the bubbles and tissue, and sensitive imaging of perfusion is now possible.

At high energy, still within the normal range as applied clinically, the bubbles will disrupt in the imaging plane, and this can be used to visualize a new inflow of contrast. This technique, very useful to detect fast enhancement of tissue, is called destruction-replenishment [16, 17].

In general, ultrasound contrast agents are safe. In Europe over 6000 CEUS investigations of the prostate were reported, without any side-effects [18]. However, side-effects have been reported and the most severe were allergic reactions to the ultrasound contrast agents [19]. The most commonly reported side-effects are rare and usually transient: altered taste, pain at the side of injection and generalized flushing. A paper by Wink et al concludes that in general ultrasound contrast agents are very safe [18].

Contrast-enhanced ultrasound of the prostate

Prostate carcinoma is the most common malignancy in the male population in the western world, and accurate diagnosis and staging is still problematic [20, 21].

Transrectal ultrasound (TRUS) was introduced in 1968 by Watanabe *et al*. [22]. Currently, TRUS is mostly used for guiding systematic biopsies. At first only hypoechoic lesions were biopsied as these were presumed to be the main presentation for prostate carcinoma. However, studies demonstrated that these lesions have only a 17–57% chance of being malignant and that as many as 30% of prostate carcinomas are isoechoic [23, 24]. Therefore, the systematic biopsy protocol was introduced. Hodge *et al.* described the ultrasound-guided sextant biopsy protocol, which has become the most frequently used protocol, with sensitivity and specificity in the ranges of 39–52% and 81–82%, respectively [24, 25].

As stated previously, malignancies are associated with neovascularization and therefore an increased microvessel density (MVD). Siegal *et al*. reported an approximate twofold increase in MVD in prostate carcinoma in comparison to benign prostatic hyperplasia (BPH) [26]. In 2001 Sedelaar *et al*. correlated the histologically determined MVD in radical prostatectomy specimens with three-dimensional (3D) contrast-enhanced power Doppler [27]. On average, the areas with increased enhancement had a 1.93 times higher MVD than unenhanced areas, and all enhancing areas contained prostate carcinoma. Only small satellite lesions (1–2 mm) were not identified on CEUS. This study clearly demonstrated that the increased MVI as a result of prostate carcinoma could be visualized with CEUS (Figure 117.1), and therefore could open the doorway to targeted biopsies.

Targeted biopsies

To investigate the role of targeted biopsies, Frauscher *et al*. investigated 230 patients with a prostate-specific antigen (PSA) greater than 1.25 ng/mL and a free-to-total PSA less than 18% in whom both CEUS-guided and systematic biopsies were taken [28]. In the CEUS-guided biopsies no transition and central zone biopsies were taken; in the systematic biopsies these biopsies were taken. They found no statistically significant difference in the cancer detection rate for CEUS and systematic biopsies (56 of 69 vs 52 of 69); however, there was a significant difference when only the peripheral zone cancers were considered (56 of 62 versus 45 of 62). The Gleason scores of the carcinomas found on systemic biopsy were 4–6, while the scores of the carcinomas found on CEUS biopsy alone were 6–9. This indicates that CEUS biopsies may detect more clinically significant tumors than systematic biopsies. In this study, CEUS and systemic biopsies differed significantly in the number of biopsies needed to detect cancer. Of the 2300 systemic biopsies, 123 showed cancer, while 118 of the 1139 CEUS biopsies showed cancer (positive predictive values of 5.3% vs 10.4%). The authors concluded that CEUS-targeted biopsies detected the same number of carcinomas, but with higher Gleason scores and with fewer biopsies.

In another study, Peltzer *et al*. investigated 380 patients with a PSA between 4 and10 ng/mL and a free-to-total PSA less than 18% with CEUS-targeted and systematic biopsies [29]. There was no significant difference between CEUS and systematic biopsies (104 vs 105 carcinomas of 143 carcinomas). CEUS and systematic biopsies combined were significantly more effective in

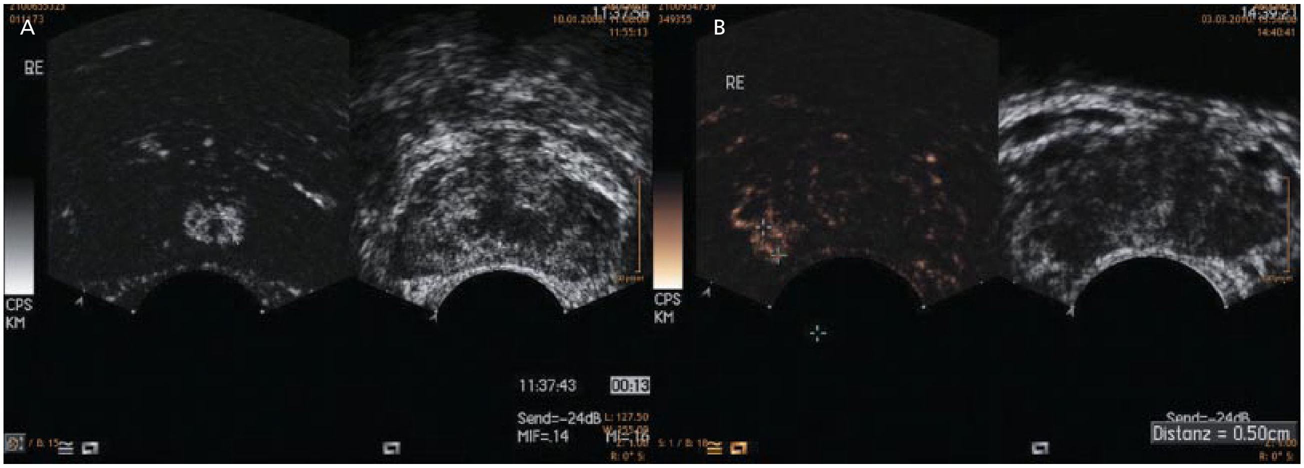

Figure 117.1 CEUS investigation of the prostate using the "cadence pulse sequence" technique. (A) An enhancing lesion is seen on the central left side and histology showed a Gleason 4 + 4 carcinoma. (B) A lesion is seen on the right side of the prostate, and histology showed a Gleason 4+3 carcinoma (reproduced by permission of Dr Ir. M. Misch, Eindhoven University of Technology).

detecting carcinoma than either modality alone. The authors concluded that for maximal detection a combination of systemic and CEUS-guided biopsies is preferred.

In 2009 Seitz *et al*. published data on CEUS in correlation with histologic specimens [30]. They included 30 patients who were scheduled for radical prostatectomy due to biopsy-proven prostate carcinoma and five patients who were scheduled for radical cystoprostatectomy due to muscle-invasive bladder carcinoma. On histologic evaluation one patient who underwent a cystoprostatectomy also showed prostate carcinoma. All patients underwent ultrasound and CEUS imaging before surgery, and afterwards the ultrasound and CEUS procedures were correlated with the histologic findings. Ultrasound identified 14 of the 31 foci and CEUS identified 22 of the 31 foci. On a patient basis there was no statistical significant association between ultrasound or CEUS and histology, but CEUS was significantly better than ultrasound in detecting carcinoma and the CEUS-enhancing tumors were significantly larger than the nonenhancing tumors. Of the foci found on CEUS, 77% were the index tumor, and of the foci found on CEUS, 86.4% were staged correctly. They concluded that CEUS correlated with histologic specimens on staging and the identification of the index tumor.

In summary, CEUS is a promising diagnostic tool for prostate carcinoma: it detects cancer as well as systemic biopsies with fewer biopsies needed, and the detected cancers are of higher Gleason score. When CEUS is compared with histologic specimens after radical prostatectomy, it frequently detects the index tumor and this tumor is mostly staged correctly. However, most CEUS studies in the diagnosis of prostate carcinoma involve relatively small populations and are single-center studies. Prospective multicenter trials are needed to confirm these results.

Use in focal therapy

CEUS can be used to guide and monitor focal therapy. Sedelaar *et al*. used CEUS to investigate the effectiveness of high-intensity focused ultrasound (HIFU) in the treatment of prostate carcinoma [31]. In this study, CEUS was compared with whole-mount histology specimens from patients who underwent a radical prostatectomy 1–2 weeks after HIFU treatment for a T1 or T2 prostate carcinoma. Overall a strong correlation of 0.98 between CEUS and pathology volumes of the lesion was found.

Atri *et al*. performed CEUS in 12 patients during interstitial laser therapy of the prostate [32]. After 1 week an MRI was performed to measure the size of the ablated prostate tissue. This measurement was then correlated with the CEUS measurement. The measured lesion sizes were identical on CEUS and MRI.

Eckersley *et al*. conducted CEUS in patients with prostate carcinoma before and during antiandrogen therapy and they compared the changes in PSA level with CEUS enhancement [33]. Within 1 week the decrease in vascular enhancement was similar to the decrease in the PSA level and this continued until 6 weeks after the start of the treatment. In four patients there was a discrepancy between the decrease in PSA level and the enhancement; the two patients with the most marked discrepancy relapsed after 6 months.

The earlier mentioned studies demonstrate that CEUS can be a potential imaging modality for the monitoring and follow-up of focal therapies in patients with local

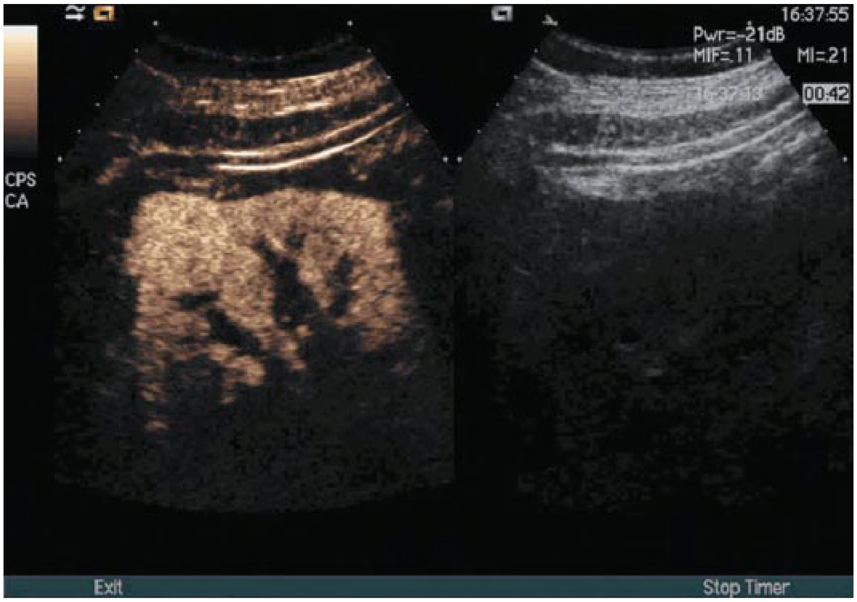

Figure 117.2 CEUS investigation of a kidney tumor. On the left side an enhancing lesion is seen.

prostate cancer. However, focal prostate cancer therapy is not yet a standard procedure because of the lack of clinical data needed to prove that proper visualization of cancer is possible.

Contrast-enhanced ultrasound in renal masses

The more frequent use of cross-sectional imaging has resulted in an increase in incidentally found renal masses. Renal masses are divided into cystic and solid masses, and cystic masses can be simple or complex. Approximately 10% of renal cell carcinomas present as complex renal cysts, but not all complex cysts are renal cell carcinomas [34–36].

Ultrasound imaging cannot differentiate perfectly between complex cysts that need surgery and those that can be observed. The enhancement characteristics of the cyst are a main feature on which this decision is made, and in most cases a contrast CT is used to image these characteristics. When a contrast CT is not possible, a contrast MRI can be used. The Bosniak classification is mainly used to characterize renal cysts [26, 27] (see Table 81.1).

CEUS can also be used to investigate enhancement characteristics, and in 2004 Thorelius used this technique for various organs [37]. In the kidney he noted that CEUS was highly sensitive in the characterization of nonvascular lesions (cysts, infraction, laceration).

Diagnosis of renal masses

The use of CEUS in the diagnostic evaluation of renal masses was described by Wink *et al*. in 2007 [38]. They performed CEUS in 18 patients with 20 masses and, if available, this was compared with the histology of the masses. Of the 13 masses for which histology was available, 12 showed a malignancy. Of the other seven masses, four were classified as Bosniak I or II(F) cysts; two as angiomyolipomas and one was suspicious for renal cell carcinoma. CEUS classified all the masses correctly and the authors concluded that CEUS is a promising technique for evaluating renal masses. Figure 117.2 shows an example of CEUS of a renal tumor.

Ascenti *et al*. used the Bosniak classification to compare CEUS with contrast CT in the classification of renal cysts [36]. They included 40 patients with one or more cysts of Bosniak II or higher and found a complete concordance between CEUS and CT in discriminating between nonsurgical and surgical cysts. Furthermore, CEUS identified 14 cysts with vascularization and CT 10 such cysts, and the general conclusion was that there was a high concordance between CT and CEUS.

Quaia *et al*. investigated 26 patients with renal masses, comparing CEUS with histology or CT [39]. Of the 26 masses found, 19 were solid renal masses: 11 solid renal cell carcinomas, seven angiomyolipomas, and one embryonal metanephric adenoma. They found that CEUS was able to differentiate as well as CT between solid renal cell carcinoma and angiomyolipoma.

A peritumoral pseudocapule is associated with a low-risk tumor, and the gold standard for its identification is currently MRI [40, 41]. Ascenti *et al*. investigated the capability of CEUS to diagnose the peritumoral pseudocapsule in 32 patients with 40 renal masses, of which 26 were renal cell carcinoma [42]. On histologic examination of the renal cell carcinomas in 14 of the cases, a

pseudocapsule was present. Conventional ultrasound detected this in three cases with a sensitivity of 21%, while CEUS detected this in 12 cases with a sensitivity of 87.5%. Ascenti *et al*. concluded that CEUS can compete with MRI in the detection of a peritumoral pseudocapsule.

Use in ablative therapies

Because of the increasing incidence of small renal masses, of which a significant number are benign, more and more nephron-sparing treatment modalities have been introduced [34, 42, 43]. Along with partial nephrectomy, ablative treatments, including cryoablation and radiofrequency ablation (RFA), can be used, and CEUS could play a role in monitoring these treatments and also during follow-up, by visualizing the resulting perfusion defects.

To our knowledge, the first description of CEUS and RFA was in 2005 in two series in pigs [44, 45]. CEUS was performed after RFA, and the identified lesions were measured and compared with the histologic measurements after removal of the kidneys. The study of Johnson *et al*. found an average difference between CEUS and histologic measurements of 0.15 cm (length), 0.26 cm (height), and 0.19 cm (width) [44]. In the study by Slabaugh *et al.*, the average difference between CEUS and histologic measurements was 0.238 cm (length), 0.422 cm (height), 0.090 cm (width), and 0.195 cm^3 (volume) [45]. Both studies concluded that CEUS can visualize RFA defects with great accuracy.

Meloni *et al*. compared CEUS with contrast-enhanced CT or MRI after RFA in 27 patients with 28 tumors. Of these tumors 27 had a hypervascular pattern and one a hypovascular pattern at baseline imaging [46]. The concordance between CEUS and CT or MRI findings after RFA was 100% for the hypervascular tumors; the one case of hypovascular tumor progression was missed on CEUS. The sensitivity, specificity, and overall accuracy of CEUS were 96.6%, 100%, and 98.1%. They concluded that CEUS is a good alternative imaging technique for follow-up after RFA.

Wink *et al*. and Zhu *et al.* have described follow-up of cryoablation with CEUS [47–49]. Zhu *et al*. performed CEUS and CT or MRI in three patients before and after cryoablation. The CEUS images demonstrated the same enhancement patterns as CT or MRI, but CEUS better visualized the arterial feeding vessels. The feasibility study by Wink *et al*. used CEUS after cryoablation of renal tumors. They found that within 5 weeks after cryoablation the perfusion defect was larger than the initial tumor, and in one patient after 1.5 years the lesion was no longer visible. These studies suggest that CEUS may be a sensitive imaging technique for follow-up after cryoablation. An example of CEUS after cryoablation is shown in Figure 117.3.

Especially for ablative treatment modalities, CEUS seems to be a potential alternative to contrast CT or MRI. The absence of perfusion can be visualized with a very high sensitivity. Again, prospective multicenter trials are needed to determine the additional clinical value of this technique.

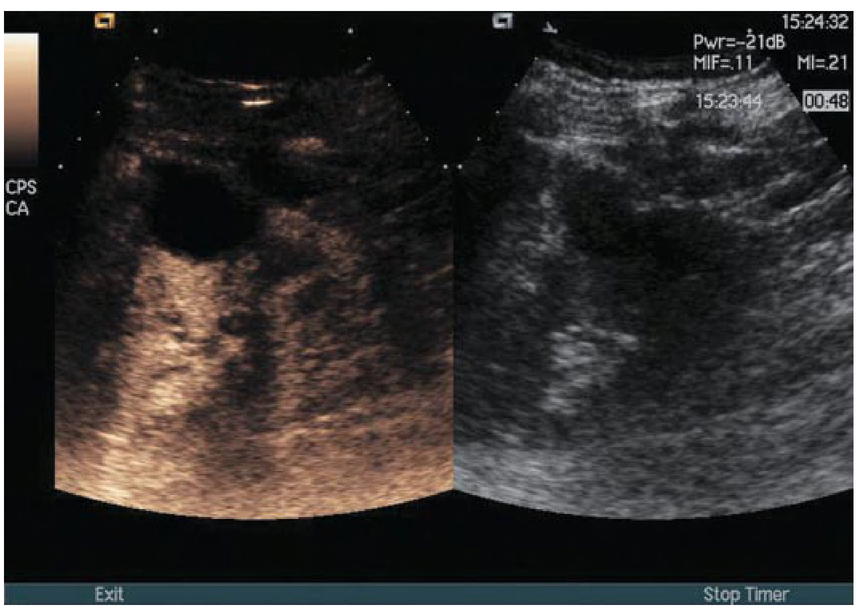

Figure 117.3 CEUS image of a kidney after cyroablation. A clear avascular zone is visible in the location where the cryoablation was performed.

Future developments

Quantification

In general, the described CEUS characteristics are the subjective determination of perfusion features by investigators, and may be subject to bias between centers and investigators. Quantification and calculation of well-defined perfusion parameters could make CEUS a more objective and reliable technique in the hands of novice users also.

A study by Goossen *et al*. indicated that the minimal time to peak enhancement was the most predictive factor to determine the most affected side with malignancy in patients with proven prostate carcinoma [50]. Van Moerkerk *et al*. stated that in 65% of the cases, computerized localization could discriminate between malignant and benign disease [51]. In both studies the CEUS quantification techniques were compared with the histology of radical prostatectomy specimens. Currently, new quantification techniques are under development that focus on the visualization of prostate cancer, and these may become useful future targeted biopsy guiding techniques [52]. An example such a quantification technique is shown in Figure 117.4.

Targeted microbubbles

Molecular imaging with targeted microbubbles has been tested in animal models [44, 45]. The bubbles used in these experiments have additional adhesion molecules built into their shells. Due to the binding of these adhesion molecules to receptors such as that for vascular endothelial growth factor (VEGF), which are over expressed in malignant tissue, sensitive imaging of malignancy becomes possible.

Wilmann *et al*. used mouse cell cultures for an *in vitro* study and tumor-bearing mice for an *in vivo* study of a VEGF-targeted bubble [53]. They compared a control contrast agent with targeted bubbles in cancer and non-cancer cells. In the *in vitro* study, significantly more targeted bubbles adhered to the cancer cells compared to the regular contrast agent (2.1 targeted bubbles/cell vs 0.1–0.01 control bubbles/cell), and significantly more targeted bubbles adhered to the cancer cells then to the noncancer cells. In the *in vivo* study the targeted bubbles showed significantly higher contrast enhancement than the control bubbles. In a blind experiment Lyshchik *et al*. compared CEUS using a VEGF-targeted bubble with a control bubble agent in tumor-bearing mice [54]. The targeted bubbles showed a statistically significantly higher enhancement then the control bubbles.

A new targeted contrast agent, referred to as BR55, was introduced by Bracco Imaging SpA (Milan, Italy), and has demonstrated increased enhancement of human tumor cells in a rat model [55]. BR55 is specially designed for use in humans, and therefore we can expect that these ultrasound molecular imaging techniques will shortly be available for use in humans.

As well as adding adhesive molecules to the shell, it is possible to add other molecules to the shell or the inside of the bubbles. By loading bubbles with drugs and using high-output ultrasound to destroy the bubbles, local drug delivery is possible. *In vitro* and *in vivo* experiments show that this is feasible. In 1997 Bao *et al*. used hamster cells to transfect DNA and fluorescent dextran into the cells using ultrasound with and without contrast [56]. Cells exposed to the contrast contained the DNA and fluorescent dextran, while those that were not exposed to the contrast did not. Haag *et al*. used ultrasound with a contrast agent to asses if a DNA particle could be transfected into human prostate

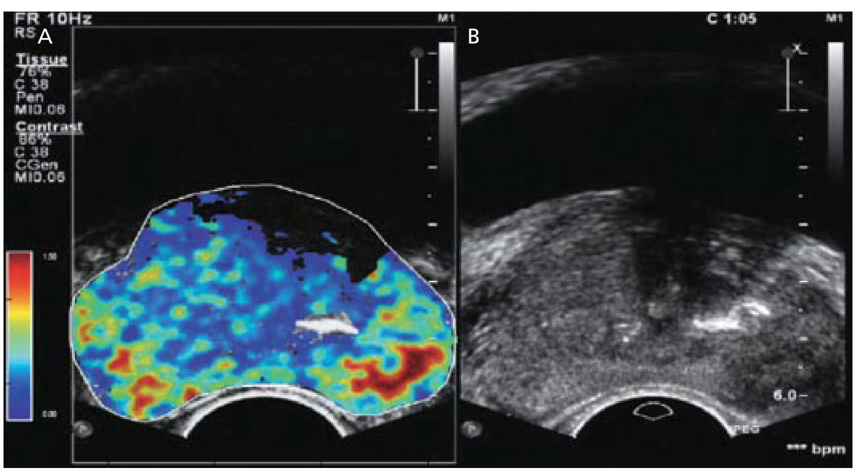

Figure 117.4 Quantification of CEUS with the technique "diffusion modeling/analysis.". (A) CEUS with an overlay of the quantification results. The red areas are predicted to have a high chance of being malignant. (B) Normal CEUS image (both images reproduced by permission of Dr Ir. M. Misch, Eindhoven University of Technology).

carcinoma cells [57]. Analysis of the cells revealed that 49% of the cells contained the inserted DNA particles. This group then used ultrasound with a contrast agent intratumorally or intravenously to transfect DNA into mice with prostate carcinoma. At 24 h after the ultrasound, the mice were sacrificed and the tumors were examined for the transfection of the DNA. Again, the tumor cells contained the transfected DNA, proving that *in vivo* DNA delivery though the use of ultrasound is possible.

The use of bubbles and ultrasound, and the bubble destruction process, have the additional benefit of higher uptake as the added molecules more easily cross the cell membrane [58].

Fusion imaging

CEUS technology has improved over recent years, and has become a technique by which tissue perfusion can be imaged in detail. New MRI developments, particularly for prostate cancer detection and localization, also show promising results in centers of expertise. Therefore, the fusion of recorded MRI studies and realtime CEUS could be an option to combine the "best" of both techniques. In the same way, CT and ultrasound or CEUS can be combined. In 2008 Ukimura *et al*. used fusion imaging to guide RFA treatment of renal cell carcinoma [59]. They found that fusion imaging allowed excellent anatomic visualization and a precise direction of RFA. In 2008 Xu *et al*. explored the use of fusion imaging in the diagnosis of prostate carcinoma [60]. They used previously recorded MRI images fused with real-time TRUS of the prostate to guide biopsies in 20 patients, and concluded that the fusion of these images provides clinically acceptable accuracy.

Conclusions

In centers of expertise, CEUS has become a perfusion imaging technique that shows promising results in the diagnosis and treatment of prostate and kidney cancer. The available results for monitoring and follow-up of focal (ablative) treatment modalities are also very encouraging. Therefore, an urgent need exists for larger prospective and multicenter studies that should provide the final evidence that CEUS has an additional clinical value.

CEUS is a still under development, but with the future introduction of targeted molecular imaging, it may play an even more significant role in the diagnosis and treatment of urologic malignancies. Fusion of different imaging techniques is under development, and it is expected that these techniques will allow even more accurate imaging of malignancies.

CHAPTER 118

Endorectal MRI: Use in Prostate Cancer

Abhishek Srivastava, Sonal Grover, Prasanna Sooriakumaran & Ashutosh Tewari

LeFrak Center of Robotic Surgery and Institute of Prostate Cancer, James Buchanan Brady Foundation Department of Urology, Weill Medical College of Cornell University, New York, NY, USA

Introduction

Prostate cancer is the commonest nondermatologic cancer in men in the Western world [1]. Autopsy studies have shown that approximately 30–50% of men worldwide harbor latent prostate cancer by their 50th birthday and over 80% of men have cancer by their 80th year of life [2]. Although many with prostate cancer die from other causes, it is still the second leading cause of cancer death in men in the US after lung cancer, with 28 600 deaths in 2008 [3]. As its prevalence increases along with the increasing life-expectancy in men, prostate cancer is likely to become an even more critical healthcare issue in the future.

In the 1960s, digital rectal examination (DRE) was the mainstay of prostate cancer diagnosis. The DRE cannot diagnose microscopic cancers and is best at identifying larger cancers that have often spread beyond the confines of the gland. It is also not a very specific test, often being positive with a number of benign diagnoses (e.g. prostatitis, benign prostatic enlargement). In the late 1980s, the prostate-specific antigen (PSA) assay was developed. PSA cannot be used as an absolute diagnostic tool for prostate cancer as its levels can be elevated in various other pathologies, such as benign prostate enlargement (BPE), prostatitis, and prostatic infarct [4–6]. Even when DRE and PSA are combined, the sensitivity and specificity for diagnosing prostate cancer remain low (the exact values depend on the PSA threshold level chosen). Investigators have thus attempted to use other PSA characteristics, such as PSA velocity, PSA density, and free-to-total PSA ratios, none of which has reached widespread clinical uptake due to their failure to improve the accuracy of PSA to a sufficient degree; the ROC AUC (receiver operator curve area under the curve) remains less than 85%.

Given the significant limitations of DRE and PSA to diagnose prostate cancer, imaging modalities have been evaluated. Transrectal ultrasound (TRUS) is the most commonly used and readily available modality. However, it provides little advantage over DRE and PSA, with a positive predictive value (PPV) of 52.7%, negative predictive value (NPV) of 72%, and accuracy (ROC AUC) of 67% [7]. The value of TRUS in the local staging of a tumor is also poor, and is no more accurate than DRE for the purpose of detecting local tumor extension according to a multi-institutional study [8]. Hence, in current practice, TRUS is limited to guidance of prostatic biopsies.

Magnetic resonance imaging (MRI) was developed by Mansfield and Lauterbur, who won the Nobel Prize in Physiology or Medicine in 2003 for their pioneering work. MRI is based on the principle of nuclear magnetic resonance, which won Bloch and Purcell the Nobel Prize in Physics in 1952. It has widespread applications in human radiology, including prostate cancer imaging. Endorectal coils are used either alone or in combination with phased-array surface coils. They have enabled increasingly accurate evaluation of extraprostatic extension (EPE) and seminal vesicle involvement (SVI) of prostate cancer [9–11]. Today, endorectal MRI (eMRI) has applications in diagnosis, staging, pretreatment planning, and follow-up of prostate cancer. Recently, the addition of functional sequences (perfusion imaging,

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

diffusion imaging, and spectroscopy) to the morphologic T2-weighted imaging has enhanced the ability of MRI to differentiate between tumoral and normal tissue [12–19]. Endorectal coils are preferentially used in obtaining these functional sequences as they better receive signals close to the prostate, and thus a higher signal-to-noise ratio (SNR) can be obtained without sacrificing an already low spatial resolution.

Protocol for endorectal imaging

MRI is a noninvasive modality that uses magnetic and radio waves together with a computer to create cross-sectional images of various parts of the body. Food and fluids are restricted from midnight the night before until after the procedure is complete. For prostate imaging, the bowel is prepared using an enema. Before the procedure, per rectum examination is performed to assess the area for safe probe insertion. The endorectal coil or balloon coil has a flexible shaft with a small balloon at one end. Once inserted, the balloon is filled with air until it comes into contact with and conforms to the size and shape of the prostate. A shot of glucagon may be given to the patient to keep the bowels from moving. The patient is placed in the supine position and kept still while the MR images are taken.

Role of endorectal MRI in early diagnosis of prostate cancer and in patients with a rising prostate-specific antigen

Early diagnosis of prostate cancer

In this era of PSA screening, patients with negative prostatic biopsies and a continually rising PSA are encountered more frequently [20]. Established strategies for managing such patients include a repeat biopsy scheme (10–12 cores), saturation/template biopsy (>12 cores), or continued PSA monitoring. None of these strategies is ideal; the first two are invasive and may still miss significant cancer, while the third does not deal with what steps to take if the PSA continues to rise. A noninvasive imaging modality would constitute a major breakthrough in prostate cancer diagnostics. eMRI shows promise in this area. Studies have shown that MRI in patients with one set of negative biopsies and a continuing rise in PSA levels is better than repeat TRUS biopsy [21, 22]. In a screening population of 92 patients, Comet-Batlle *et al*. have demonstrated 80% sensitivity, 76.1% specificity, 55.6% PPV, 91.1% NPV, and 77.2% accuracy for MRI, compared to 85% NPV of a negative octant biopsy for prostate cancer [23]. Cheikh *et al*. reported 82.6% sensitivity and 100% NPV of T2-weighted MRI when evaluating visible suspicious areas prior to repeat TRUS prostate biopsy [24]. An MRI showing "no evidence of disease" in a patient with a marginally raised PSA would seem to offer a similar level of reassurance as two sets of prostate biopsies that are reported as "no cancer detected" [23].

MRI-targeted prostate biopsy

Another approach for patients with negative biopsies and a continually raised PSA is to use MRI-targeted biopsy. In targeted biopsies the eMRI, done prior to the TRUS, is used to direct biopsies towards suspicious lesions. Targeting biopsies provides the advantage of detecting prostate cancer that might not have been detected by systematic sampling alone, particularly those outside the peripheral zone [21, 22, 25, 26]. In a study by Perrotti *et al*. in a cohort of 33 patients, MRI had 85.7% sensitivity, 65.5% specificity, 40% PPV, 94.4% NPV, and 69.7% accuracy. They found that a positive eMRI (moderate or high suspicion) indicated a 11.3-fold increased risk of positive biopsy [27]. In a similar study, Beyersdorff *et al*. found that targeting biopsies to suspicious areas on MRI led to a sensitivity of 83%, specificity of 62%, and PPV of 50% for detection of cancer [21].

Sciarra *et al.* in a prospective study on 180 men with prostate cancer assessed the role of magnetic resonance spectroscopy imaging (MRSI) and dynamic-contrast enhancement magnetic resonance (DCE-MRI) in targeting biopsies in patients with persistently elevated PSA levels with prior negative biopsy, and compared the results with those obtained with a second TRUS-guided biopsy [28]. On the repeat biopsy, prostate cancer was found in 22 of 90 men (24.4%) who had second TRUS-guided biopsy compared to 41 of 90 men (45.5%) ($P = .01$) who had MRSI–DCE-MRI targeted biopsy. MRSI had 92.3% sensitivity, 88.2% specificity, 85.7% PPV, 93.7% NPV, and 90% accuracy; DCE-MRI had 84.6% sensitivity, 82.3% specificity, 78.5% PPV, 87.5% NPV, and 83.3% accuracy; and the association MRSI plus DCE-MRI had 92.6% sensitivity, 88.8% specificity, 88.7% PPV, 92.7% NPV, and 90.7% accuracy for predicting prostate cancer detection. Therefore, the combination of MRSI and DCE-MRI has a higher potential to target biopsy to cancer foci in patients with a previously negative TRUS biopsy.

Although the results of this approach are encouraging, it also has certain limitations. Sometimes the lesions detected on MRI are not visible on ultrasound, making it difficult to target the biopsy to the site of the lesion on MRI. This causes false-negative results due to errors in guidance. The underlying problem is that biopsies cannot be taken in realtime under MR guidance, and it is difficult to precisely localize all MR-suspicious areas with TRUS.

Role of endorectal MRI in patients with clinically localized prostate cancer

Prostate cancer detection

A TRUS-guided prostate biopsy targets the peripheral zone of the prostate; thus, tumors in the anterior fibromuscular stroma, transition zone or apex are often missed. Also, only a small proportion of the peripheral zone itself is sampled by the TRUS-guided biopsy, and the overall NPV of the biopsy is 70–80% [29].

With eMRI, the detection of prostate cancer depends on the type of imaging sequence used. On T1-weighted images, the prostate demonstrates homogenous medium signal intensity. On T2-weighted MR images, prostate cancer is shown most commonly with decreased intensity within the high signal intensity normal peripheral zone. The ability of MRI to localize disease within the gland varies, with sensitivities from 37% to 96% in published studies; this variation is due to a number of factors: the criteria used to define the significant tumors, the method of analysis, and whether the reference standard was TRUS biopsy or whole-mount histology. The specificities range from 21% to 67% [30]; therefore, MRI has reasonable sensitivity but poor specificity for prostate cancer detection [21, 31, 32]. Furthermore, the accuracy of cancer detection also varies according to the size of the tumor, location of the tumor, and biopsy-associated changes, which can cause incorrect estimation of tumor presence and extent. It is notoriously difficult to distinguish biopsy-associated hemorrhage from tumors on T2-weighted images. Therefore, an interval of at least 6 weeks is generally recommended between prostate biopsy and MRI [33].

With the widespread introduction of PSA testing, there has been a shift towards detection of prostate cancer at an early stage of disease. Roethke *et al*. studied the tumor size-dependent detection rate of eMRI and found greater accuracy for detecting large and high Gleason score tumors, than for small and low-score tumors. Tumors smaller than 0.3 cm were not visualized on MRI (detection rate 0%); the detection rate for tumors between 0.5 and 1 cm was 13%, for tumors of 1–2 cm it was 45%, and for tumors of greater than 2 cm it was 89% [34]. The inability of MRI to detect tumors smaller than 0.5 cm is of uncertain value. Such small foci are often regarded as clinically insignificant and it is known that only the volume of the largest focus of cancer (the "index tumor") in men undergoing radical prostatectomy influences PSA failure, while small foci of less than 0.5 cm^3 seem to have little or no effect [35, 36]. However, these small foci may represent potential for clinical significance with increasing time. The problem is that the size of the tumor has not been shown to correlate well with need for treatment and thus, the rationale for active surveillance remains to be proven. However, a study by Shukla-Dave *et al*. in 220 men with localized, low-risk prostate cancer showed that models incorporating T2-weighted MRI with clinical and biopsy data performed significantly better than models without imaging data in identifying men with prostate cancer of less than 0.5 cm^3 cancer and Gleason score of 6 or less [37].

The specificity of MRI is decreased by its inability to distinguish between the low T2 signal intensity that is associated with tumors from other pathologies, such as prostatitis, postbiopsy hemorrhage or treatment changes [38].

MRI was initially thought to be less effective in the detection of prostate cancer in the transition zone. Recent studies, however, have shown that MRI has roughly equal accuracy throughout the prostate, and good sensitivity and specificity (75% and 87%, respectively) in detecting transition zone cancers as well [39]. Akin *et al*. suggested that indicators of transition zone cancer include homogenous low signal, lenticular shape, and invasion of the anterior fibromuscular stoma [39].

Prostate tumor burden

It is often found that pathologic staging, surgical margin status, histologic grade, and tumor volume are powerful predictors of individual prognosis and prostate cancer biology [40–42]. Tumor volume estimated from prostatectomy specimens correlates with the risk of failure after radical prostatectomy [43], and tumor volumes less than 0.5 cm^3 are considered to be insignificant [44]. Tumor volume measurement may therefore provide important information for therapy planning. Huge variation has been noted across various publications in measuring tumor volume using eMRI. Jager *et al*. reported poor correlation between tumor volumes determined from MR images and pathologic sections: the actual tumor volume was predicted within 25% of the pathologic tumor volume in only 30% of the cases. An overestimation was seen in 47% of cases and an underestimation in 23% of cases [45]. Ponchietti *et al*. found a good correlation ($r = 0.94$) between tumor volumes determined from eMRI and pathologic specimens; however, MRI tended to overestimate volumes of small tumors and underestimate volumes of large tumors despite efforts to reduce the possible sources of artifacts [46]. Kahn *et al*. showed an average of 40% discrepancy in measurement of tumor volume for unenhanced MRI [47]. Nakashima *et al*. used tumor diameter as the measure of tumor volume and found that maximum tumor diameter on eMRI correlated significantly with that shown by histologic examination, especially for tumors greater than 1 cm in diameter, although it did not correlate significantly with the histologic diameter of tumors of less than 1 cm [48]. Therefore,

eMRI would be more useful to stratify patients with prostate cancer volumes of greater than 1 cm^3.

Local prostate cancer staging

Different classifications have been applied to stage prostate cancer, but only the TNM (tumor, node, and metastasis) system is widely used worldwide. The TNM staging system uses imaging to define presence and extent of prostate cancer. The goal of imaging technology is to differentiate between diseases confined to the gland (T1–T2) and locally invasive disease (T3). Further, in locally invasive disease it is important for therapeutic planning and prognostication to distinguish those tumors penetrating the prostate capsule but sparing the seminal vesicles (T3a) from those invading the seminal vesicles (T3b). Patients with organ-confined disease can be treated with radical prostatectomy or radiation therapy, whereas those with more advanced disease are treated with radiation therapy, hormonal therapy or a combination of these [49, 50].

DRE and PSA level assessment are not accurate in determining the local tumor stage, with underestimations as high as 40–60% [51]. Among the imaging techniques, TRUS can accurately detect locally advanced tumors but is not sensitive enough to detect the initial extraprostatic spread across the capsule or into the seminal vesicles in clinically confined lesions. The introduction of eMRI has dramatically improved the spatial resolution compared to the conventional phased-array body coil [52–55]. As a result, there has been a significant increase in the ability to correctly define tumor location and extent, enhancing the ability to tailor the treatment selection to ensure complete eradication of cancer while minimizing treatment-related morbidity.

Prostate cancer on eMRI can be diagnosed as intracapsular when the normal hyperintense prostatic tissue is seen between the tumor and the capsule or when there is a clear delineation of the capsule itself, despite the vicinity of the tumor. On the other hand, any bulging or irregularity in the contour of the gland, hypointense focal thickening of the capsule at the capsular margin or at the edges of the tumor, and retraction of the capsule adjacent to the tumor are highly suspicious signs for capsular penetration [56].

Staging accuracy

MRI is now considered by many to be the most exact imaging modality for staging prostate cancer, including capsular penetration, pelvic lymph nodes, and pelvic bone metastasis [57–59], invasion of neurovascular bundles (NVBs), and SVI [56, 60]. Precise analysis of all of these features is crucial for accurate treatment planning.

In a study examining the local staging accuracy of 3-T eMRI, Futterer *et al*. reported high accuracy levels of 94% and 81%, sensitivities of 88% and 50%, and specificities of 96% and 92%, for an experienced and a less experienced radiologist, respectively [61]. Although there has been a wide variation in the reported accuracy of prostate cancer staging by MRI, this has improved with increased reader experience, maturation of MRI technology (faster imaging sequences, more powerful gradient coils, and postprocessing image correction), and improved understanding of morphologic criteria to diagnose EPE and SVI.

Extraprostatic extension

EPE is suspected on eMRI in the presence of capsular penetration, bulging of the prostatic contour caused by the tumor, stranding in the periprostatic fatty tissue, tumor tissue in the extraprostatic tissue, asymmetry of the NVBs, and obliteration of the rectoprostatic angle. The presence of EPE is one of the most important prognostic factors in patients with prostate cancer and has been well correlated with treatment failure after radical prostatectomy, particularly if a nerve-sparing surgical technique is used. Pretreatment awareness of the presence and extent of EPE is important for treatment selection and management planning.

Yu *et al*. studied 77 patients with stage pT2 and pT3 prostate cancer and reported obliteration of the rectoprostatic angle and asymmetry of the NVB as the MRI imaging features most indicative of EPE [62]. Furthermore, radiologist experience was determined to be an important factor in interpreting MRIs and contributed to interobserver variability. Wang *et al*., in their study on 344 patients, found that eMRI outperformed biopsy Gleason score, clinical stage, preoperative PSA, greatest percentage of cancer and percentage of cancer-positive core specimens in all core biopsy specimens, and the presence of perineural invasion in the pretreatment evaluation for presence of EPE, with a sensitivity of 42.2% and specificity of 95.4% [63].

Seminal vesicle involvement

MRI is instrumental in identification of SVI, because of its excellent soft tissue resolution. SVI on MRI appears as low signal intensity within the seminal vesicle and/or lack of preservation of normal seminal vesicle architecture. These features along with the presence of tumor at the base of the prostate and EPE are highly predictive for the presence of SVI [64].

Sella *et al*. reported that MRI, when interpreted by dedicated genitourinary radiologists experienced in prostate imaging, can accurately predict SVI [64, 65]. They compared the nomogram predictions for SVI with

and without eMRI findings and proposed that an incremental value was added by eMRI with ROC AUC of 0.87 (87%) and 0.80 (80%), respectively ($P < .05$) [66].

Role of endorectal MRI in clinical decision-making

Preoperative decisions

The success of radical prostatectomy is measured by both oncologic and functional outcomes, including postoperative rates of urinary continence and return of erectile function [67]. Approximately 50% of men with a positive surgical margin (PSM) may have biochemical recurrence at 10 years after radical prostatectomy [68]. The risk of a PSM is influenced by the surgical approach, location and extent of disease (i.e. presence of EPE), with reported rates ranging from 6% to 41% in modern surgical series [40, 69–71]. EPE is a microscopic phenomenon; therefore, its presence and location is difficult to predict using both clinical and preoperative pathologic parameters alone. eMRI, due to its ability to spatially characterize the location and extent of disease, can significantly improve the predictive capabilities of clinical and pathologic parameters for the presence of EPE [63, 72]. The decision to preserve or resect the NVB responsible for erectile function is often difficult and is based upon preoperative clinical and pathologic characteristics, as well as intraoperative findings. MRI can provide surgeons with a better assessment of risk for EPE in the area of the NVB along the posterolateral aspect of the prostate. This allows for an opportunity to preoperatively alter the surgical approach to improve cancer control, while preserving periprostatic tissue important for recovery of urinary and sexual function. Hricak *et al*., in their series of 135 patients undergoing radical prostatectomy, found that by reviewing preoperative endorectal MR images surgeons were more accurately able to decide whether or not to preserve the NVB during surgery [73]. Patients were evaluated with MRI preoperatively by an experienced radiologist. Their findings were then compared to the surgeons' clinical judgment during surgery as well as to histopathologic findings. They found that when the surgeon decided to spare the NVB, MRI confirmed that decision in 84% of cases and this was correct 96% of the time. MRI results changed the surgical plan in 78% of high-risk patients (>75% risk of EPE on Partin tables) and was correct in 93% of cases. Recently, in another study, 75 patients with prostate cancer from 2004 to 2007 were evaluated with preoperative MRI, which showed a sensitivity of 92% and specificity of 100% for the detection of EPE/NVB involvement [74]. MRI findings favored NVB preservation in 67% of patients with a high clinical probability of EPE, and opposed NVB preservation in 33% of patients with low probability; these findings were correct 100% of the time. Therefore, eMRI is useful in predicting the absence of tumor in the area of the NVB in patients with low and intermediate risk.

Additionally, the ability of eMRI to visualize a large anterior transition zone or apical cancer allows for surgical modification of where the dorsal vein complex is divided and how to dissect the prostatic apex in order to improve local cancer control in areas at risk for EPE as well as to reduce PSM rates. Further, the presence of prominent apical periprostatic veins on eMRI has been strongly associated with increased intraoperative blood loss and may assist in predicting men at risk for substantial intraoperative hemorrhage [75].

Focal therapy decisions

There are very few studies of MRIguided focal ablative modalities. The ability of MRI to accurately stage and characterize the disease may play a critical role in its utilization for delivering focal therapy. With additional development, MRI-guided focal therapy may become a viable option for the management of low-volume and low-risk prostate cancer. Lindner *et al*. showed the feasibility of image-guided laser ablation of small-volume prostate cancers in their initial experience with MRI-planned, ultrasound-guided photothermal focal therapy on 12 prostate cancer patients [76]. In a further study, they performed MRI-planned, ultrasound-guided focal laser therapy (FLT) followed by radical prostatectomy and found no viable tumor in whole-mount histopathologic examination of the ablated area [77]. Raz *et al*. used outpatient inbore MRI-guided focal laser ablation for low-risk prostate cancer. In their trial, MRI-guided FLT allowed for visualization of the tumor, realtime guidance of the thermal device to the target, and monitoring and control of the zone of ablation and surrounding tissue during treatment. MRI allows the immediate confirmation of the success of the treatment and, if necessary, immediate repeat therapy [78]. Although further trials will be necessary to define the safety and oncologic efficacy of this outpatient procedure, its refinement may result in an inexpensive, minimally invasive alternative to current active therapies.

Role of endorectal MRI in patients with biochemical recurrence

Recently, eMRI has proven capable of detecting local recurrence in many patients with a rising PSA but no palpable tumor on DRE. Silverman and Krebs demonstrated the potential of eMRI in the evaluation of local recurrence following prostatectomy with excellent sensitivity (100%; 95% CI 89–100%) and specificity (100%); 95% CI 69–100%) [79]. A study by Sella *et al*. confirmed

the high efficacy of MRI (sensitivity for detecting a recurrence was 95% and specificity 100%). In patients with recurrent cancer after radiation therapy, MRI has shown reasonable accuracy in tumor detection, including the detection of EPE and SVI [80].

MRI has been shown to be superior to TRUS in detecting local recurrences of prostate cancer. In addition to detecting local recurrence in the perianastomotic and retrovesical regions (the sites also well identified on TRUS) [81], it can also detect recurrences occurring elsewhere in the pelvis, such as at the site of retained seminal vesicles or at the lateral and anterior surgical margins, which together account for 30% of local cancer recurrences [82]. MRI, therefore, has the potential to direct a transrectal biopsy to these sites and thus may lead to a better diagnostic yield than TRUS. An additional benefit of MRI over TRUS is the ability to concomitantly evaluate pelvic lymph nodes and osseous structures, thus detecting all sites of pelvic relapse in a single examination.

Recent advances in imaging using endorectal MRI

MRI-guided biopsies

MRI provides superior anatomic detail compared to computed tomography (CT) and TRUS; hence, a combination of tissue biopsy and MRI is a more sensitive tissue sampling tool. Stereotactic placement of the needle under MRI guidance helps to target the suspected tumor site, and allows volumetric verification and documentation of the actual biopsy location, which can be used for future intervention [83]. D'Amico *et al*. were the first to successfully perform MRI-guided prostate biopsy using the transperineal approach; they did this in a patient who had previously undergone proctocolectomy [84]. Subsequently, Susil *et al*. developed a transrectal system in a canine model, which enabled precise MRI guidance, accurate targeting, and intervention monitoring [85]. Beyersdorff et al. performed MRI-guided prostate biopsies in 12 patients in a closed 1.5-T MRI unit [86]. They used a biopsy device that was compatible with MR and consisted of a needle guide that could be visualized under MRI and manipulated mechanically from outside the MRI unit. They showed that the device enabled the MRI-guided core-needle biopsy of areas suspicious for cancer. More recently, Susil *et al*. demonstrated the feasibility of a system that provides transrectal needle access to the prostate during direct imaging with a 1.5-T MRI unit for prostate biopsy [87].

MRI-guided prostate biopsy seems to be a promising technology, especially in individuals with previous negative TRUS-guided biopsies. It not only enables direct visualization during diagnostic and therapeutic procedures, but can also provide direct temperature monitoring (during MR thermometry) to ensure adequate treatment [88, 89]. The main drawback of MRI-guided biopsy is the magnetic environment, which makes interventional procedures complex, leading to prolonged occupancy of the MR suite, increased costs, and patient discomfort because of procedural positioning. Another issue with MRI-guided biopsy is the need for motion correction during the biopsy procedure.

Magnetic resonance spectroscopy

MRSI increases the sensitivity and specificity of MRI by analyzing the metabolic profile of discrete voxels within the prostate [16, 88]. Intraprostatic tumor growth is associated with increased cell membrane turnover and increased cell proliferation, which leads to an increase in cellular choline and a decrease in citrate levels [90]. Wefer *et al*. compared MRSI and MRI and found that MRSI alone had a higher sensitivity (76%) than T2-weighted MRI alone (67%), but a lower specificity [38]. However, the accuracy in diagnosing prostate cancer is highest when anatomic information from MRI and metabolic information from MRSI are combined [16, 88]. Further, another study combining data from MRI/MRSI with clinical and pathologic data found the combined model to be superior to purely clinical models at predicting the probability of insignificant prostate cancer [37]. Recently, several studies have also analyzed the effects of adding data from MRI/MRSI to conventional staging nomograms. In a study on 229 patients who underwent MRI and 383 who underwent combined MRI/MRSI prior to radical prostatectomy, the radiologic findings contributed significant value to the standard nomogram for predicting prostate-confined disease [72].

MRSI has potential as a noninvasive method of assessing tumor aggressiveness and its sensitivity is higher for detecting high-grade tumors. Zakian *et al*. studied the relationship between Gleason score as a measure of tumor aggressiveness and MRSI volumetric and metabolic data, and found that the ratio of creatinine plus choline to citrate positively correlates with prostate cancer and can predict the aggressiveness of the tumor [91]. They also found that MRSI detected only 44% of Gleason score 3 + 3 tumors, compared to 90% of Gleason score greater than 7 cancers.

MRSI can detect transition zone tumors in about 80% of cases; this is significantly higher than with T2-weighted MRI [39]. Coakley *et al*. found an improved accuracy in tumor volume measurements when combination of MRSI/MRI was used [92]. Yu *et al*. also demonstrated that use of spectroscopic imaging decreases interobserver variability and, for less experienced radiologists, improves the detection of EPE [58].

MRSI can also supplement biopsies as a method of detecting both primary and recurrent cancers [30, 38] and to guide biopsies [93, 94]. Due to its higher sensitivity in detecting cancer compared to sextant biopsies, especially when a tumor is localized at the apex where biopsies may not sample [38], it can potentially be used to follow-up patients who have undergone ablative therapy. Parivar *et al*., in their study on 25 patients who had cryotherapy for prostate cancer, found that MRSI detected all recurrent foci of tumor [95]. Another study of nine patients with recurrent prostate cancer after radiation therapy found that MRSI and MRI was both superior to biopsy at detecting recurrent disease, with sensitivities of 77% and 68%, respectively [93]. However, they also reported a significantly lower specificity of MRSI (78%) compared to conventional MRI, DRE, or sextant biopsy, which was attributed to postradiation metabolic changes in the normal prostate. Therefore, the authors suggested that MRSI may be used to supplement other techniques to detect recurrent cancer or guide biopsies or treatment by localizing tumor [93].

Dynamic contrast-enhanced MRI

Jager *et al.* first demonstrated significant improvement in prostate cancer detection with DCE-MRI in 1997. Detection increased from 57% with T2-weighted MRI alone to 73% when combined with DCE-MRI. Specificity remained fairly high at 80% [96]. Schlemmer *et al.* demonstrated a sensitivity improvement from 79% to 89% in the peripheral zone [97]. A maintained high sensitivity was further confirmed in studies by Ito *et al.* [98] and Hara *et al.* [99].

The DCE profile of a given imaging voxel (3D pixel) over time offers important information about blood flow, capillary leakage, and other physiologic processes that occur in cancerous lesions. Gadolinium-based contrast agents are used because they are diffusible (passing through capillaries) and are nonlipophilic (allowing them to remain extracellular). With recent advances in faster imaging, postprocessing hardware, and mathematical modeling, DCE-MRI has shown significant expansion in the field of prostate imaging.

DCE-MRI has promising application in the prostate and in various other organs/tissues as well, because it can detect angiogenesis (neovascularization) and microvascular properties in glandular tissues. During the cancerous process, not only is there angiogenesis, but the structure and orderly organization of these blood vessel networks are also disrupted. The newly formed blood vessels have leaky endothelia and disrupted barriers, which result in increased permeability of vessels and extravasation of the contrast. DCE occurs on a microvascular level and MRI can visualize the compartmentalization of tissue into the vascular and extravascular–extracellular space (EES). DCE-MRI allows measurement of contrast diffusion across the vascular endothelium and capillary boundaries, enabling extraction of multiple physiologic parameters that are essential for better detection, localization, and characterization of prostate malignancy.

During DCE-MRI, T1-weighted sequences are repeated before, during, and after the injection of the contrast, for a specified period of time. Most commonly, the injection of low molecular weight gadolinium is followed by serial T1-weighted three-dimensional (3D) MR image acquisitions. The temporal resolution of the dynamic acquisition for prostate imaging varies widely from 1–2 s up to 95 s, being mostly in the range of 2–20 s/dynamic phase.

Cancers can demonstrate a large, early enhancement followed by a quick washout time–intensity curve. Although this pattern can be predictive of prostate cancer, it is not reliable enough for accurate, reliable diagnosis. This qualitative assessment of contrast enhancement time–intensity curves is often used with DCE-MRI, but has limitations in terms of generalization across protocols, scanners, and other factors contributing to the MR signal intensity, including contrast agent type and dose, and MRI sequence type and settings. Hence, there is a need for quantitative modeling and assessment to provide a consistent, standardized image acquisition technique and interpretive diagnostic methodology.

The most accepted quantitative approach is the pharmacokinetic (PK) model that converts enhancements (signal intensity changes) seen on the MR images into contrast concentrations, then calculates physiologic parameters, on a voxel-by-voxel basis, which provides standardized and reliable information about tumor physiology. As discussed by Alonzi *et al*., the PK model describes the contrast exchange between the following four main compartments: blood plasma, whole-body extracellular space, tumor leakage space, and contrast elimination from blood through kidneys [100]. In clinical practice, diagnostic interpretation using a quantitative method such as PK modeling is performed using computer-assisted diagnosis (CAD) software that performs the image analysis postprocessing.

Diffusion-weighted MRI

Diffusion-weighted imaging (DWI) is a method of obtaining molecular and cellular information regarding the movement and functional environment of water in the prostate tissue. By measuring the microdiffusion of water in the intra- and extra-cellular spaces, DWI can calculate an apparent diffusion coefficient, which reflects compartmental shifts in water, membrane permeability, and cellular density, all of which may be altered in

cancerous tissue [101]. Cancerous prostate tissue has an increased cellularity, which lowers the apparent diffusion coefficient compared to the normal prostate tissue, both in the peripheral zone [102] and in the transition zone [103], in turn causing a reduction in the flow or diffusion of water [102, 103]. Several studies have analyzed the value of adding DWI to T2-weighted MRI and MRSI, and have found increased sensitivity (54%–98%) and specificity (58%–100%) [17, 101, 104]. Kim *et al*. proposed that combined DWI/T2-weighted imaging is more sensitive for predicting recurrent cancer after radiation therapy compared to the conventional T2-weighted imaging alone [105]. More recently, Park *et al*. reported that DWI is useful in the evaluation of patients with persistently elevated PSA values but negative prostate biopsies, as it is more sensitive than T2-weighted MRI in localizing lesions [106]. DWI has also been found to increase the accuracy of peripheral zone tumor volume assessment [107]. The major drawback, of this technology, however, is a substantial overlap of apparent diffusion coefficient (ADC) values between malignant and normal prostatic tissue and a marginal SNR. At present, modern 3-T MRI systems are under investigation for their utility in increasing SNRs for DWI [105]. Early studies with this technology report a high sensitivity (94%) and specificity (91%) in the peripheral zone, and a similarly high sensitivity (90%) and specificity (84%) in the transition zone [108]. Although, preliminary studies are promising, future research will further elucidate the role of DWI in the diagnosis and staging of prostate cancer.

Lymphotrophic nanoparticle MRI

Another upcoming MRI-based technology is the use of lymphotropic superparamagnetic nanoparticles as a contrast agent for detection of small and otherwise undetectable nodal metastases. These nanoparticles are injected intravenously and are taken up by macrophages in normal lymph nodes. This creates a contrast between benign nodes and cancerous nodes where the macrophages have been replaced by tumor cells [109]. Unlike conventional radiologic staging, this technology does not rely on the size or shape of the lymph node and is therefore more accurate in detecting metastases. It has proven to be effective in several other cancers [109] and investigations into its potential use in prostate cancer are ongoing. Harisinghani *et al*. evaluated 80 patients who had lymphotropic nanoparticle MRI (LNMRI) prior to either pelvic lymphadenectomy or detection of metastasis on CT. They found that LNMRI can detect metastases in small lymph nodes that would be considered benign on CT or unenhanced MRI, and that there were metastatic nodes outside of the classical field of lymph node dissection in a significant number of patients [110]. They reported an increase in sensitivity of MRI from 45.4% to 100% with a specificity of 95.7%. Therefore, this technology may be of particular utility in patients who have a high risk of metastatic disease on the basis of standard staging nomograms and conventional MRI, both of which have high NPVs for detecting metastatic disease [111]. This technology is also useful for detecting recurrent cancer, as well as guiding targeted radiation therapy. In a recent study on 26 patients with recurrent prostate cancer who were candidates for salvage radiation therapy, LNMRI detected positive nodes in six patients, none of whom had enlarged nodes on axial imaging [112]. Further studies are needed before this promising technology enters in the clinical arena.

Endorectal MRI and future research

MRI/MRSI and prostate biopsy

The replacement of biopsy by MRI has not yet been advocated, but Wefer *et al*. proposed that it might be possible in some cases [38]. They compared the sensitivity of unenhanced MRI, spectroscopy, and sextant biopsy for localizing cancer to a specific sextant and found both imaging techniques more sensitive than biopsy in the detection of cancer. They concluded that "MR spectroscopic imaging is significantly better than biopsy, when high sensitivity is required." These finding were also recently confirmed by another study using T2 sequences and spectroscopy [31]. Therefore, MRI will be useful in the follow-up of focally or incompletely treated glands. Initial studies also suggest that MRI may be a superior modality for planning focal therapy. Once the diagnosis of cancer has been made, treatment might be directed at all suspicious areas on MRI.

If MRI can detect most cancers, it will be more useful to have a scan done before biopsy, especially in intermediate-risk patients. Although more expensive, MRI has many advantages over conventional biopsy. First, biopsy-induced artifacts make T2-weighted scans more difficult to interpret and overestimate cancer, a problem that is only partly mitigated by the use of spectroscopy [113]; The chances of biopsy artifact due to hemorrhage or edema can be eliminated if MRI is done prior to biopsy. Second, MRI-targeted biopsies should also increase the cancer detection rate. Although biopsies targeted at abnormal areas on MRI have a high likelihood of being positive [22, 27, 99], convincing data have not yet been produced to show that MRI-directed biopsy increases overall cancer detection rate. This could be due to lack of a study of sufficient power having been conducted. Cancer detection rates can also be increased by emerging techniques of image fusion in which ultrasound data are fused with MR scanning data [114], whether by pure image processing or coregistra-

tion using a positioning marker on the ultrasound probe. Another potential approach to this problem is MR-guided prostate biopsy [86], but this is a time-consuming technique and first needs to demonstrate clear advantages over conventional TRUS before its cost and complexity can be justified. Third, a negative MRI result should increase the NPV of a set of negative biopsies and might eliminate the need for rebiopsy. Comet-Battle *et al*. demonstrated in a screening population of 92 patients that a negative unenhanced MR scan had an NPV for cancer on subsequent transrectal biopsy of 91% [23]. A study by Perrotti *et al*. in a group of 35 patients with previous negative biopsies found that a low-probability MR scan had an NPV of 94% for repeat biopsy, with positive scans having a 40% PPV [27]. These results suggest that a negative MR scan is as reassuring for absence of cancer as a negative repeat sextant biopsy, and can eliminate the need for further evaluation. It would be even more reassuring with the addition of contrast and spectroscopy.

Multiparametric MRI

Every MRI technique has some limitations; therefore, the combination of multiple MRI techniques may address the current drawbacks of the individual techniques. Kozlowski *et al*. reported that a combination of DWI and DCE-MRI provided better sensitivity in detecting prostate cancer [115]. Combined DWI and spectroscopy increased the specificity for prostate cancer detection while retaining the sensitivity compared with MRSI alone or DWI-MRI alone [19]. Various protocols for a combined MRSI and DCE have been evaluated in multiple patient cohorts [14, 116, 117]. However, a large prospective study combining various MR techniques (T2, dynamic-enhanced, spectroscopy, and diffusion) and with a long-term follow-up has not yet been performed and must be one of the major goals of research in this field. This may not only validate the superiority of multiparametric MRI over individual techniques, but will also answer a few questions, such as what proportion of cancers can be detected using the multiparametric MRI?; what is the NPV of a scan that is normal using each sequence?; are some cancers invisible regardless of the modality used?; and are these cancers likely to be of significant size or grade?

Conclusions

The future of eMRI in prostate cancer will depend on its ability to detect prostate cancer, especially in the setting of negative biopsy findings; to determine biologic aggressiveness and predict nodal extension; and to distinguish local and distant recurrences after treatment. Conventional MRI is unlikely to yield significantly better results in the future; therefore, functional imaging is our most immediate hope with the development of molecular imaging. This will require the combined skills of scientists and physicians in the fields of molecular biology, pharmaceutical chemistry, radiology, pathology, and urology.

CHAPTER 119
Angioembolization in Urology

Ardeshir R. Rastinehad,[1] Peter A. Pinto[1] & David N. Siegel[2]

[1]Urologic Oncology Branch, Center for Interventional Oncology, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

[2]Division of Vascular & Interventional Radiology, North Shore – Long Island Jewish Health System, Long Island, NY, USA

History

In the 1970s, angiography played an integral role in the diagnosis of renal masses and has been part of the urologic armamentarium for the last 40 years. In 1979, Clayman *et al*. outlined the algorithm which relied on presurgical angiography for the diagnosis and assessment of the asymptomatic renal mass [1] (Figure 119.1). Since then, the indications and applications for angiography and embolization in urology have expanded significantly, although angiography has been supplanted by computed tomography (CT) and magnetic resonance (MR) angiography as well as venography. Angioembolization has been utilized in the treatment of varicoceles, benign prostatic hyperplasia (BPH), pelvic congestion syndrome, preoperative tumor embolization, nonischemic priapism, angiomyolipoma, and postsurgical bleeding from the prostate, kidney and bladder. The goal of this chapter is to provide an introduction to the use of angioembolization in modern urology.

Renal angiography and embolization

The indications for renal angiography and embolization have changed since 1973, when Almgard *et al.* described the first renal embolization to treat renal cell carcinoma [2]. Indications for renal embolization varied from refractory bleeding and recurring infections to nonoperative candidates for definitive therapy. Indications currently include the treatment of angiomyolipoma (AML), preoperative tumor and/or tumor thrombus embolization, control of postoperative renal hemorrhage, pretransplant embolization of native kidneys or failed allographs, patients with end-stage renal disease and uncontrolled hypertension, and arteriovenous malformations/fistulas.

Hom *et al*. investigated the use of complete renal embolization in eight patients unable to tolerate nephrectomy for varying indications (AML, poor function, and/or hemorrhage secondary to malignancy) [3]. The pediatric literature also contains reports of renal embolization as an alternative to simple nephrectomy for severe hypertension or to pretransplant nephrectomy, and for nephritic syndrome and ablation of irreversible rejected renal allograft [4]. In one series, 10 of 12 patients developed severe flank pain, which was the most significant symptom of postinfarction syndrome.

Renal embolization (Figure 119.2) of patients prior to radical nephrectomy remains controversial. Two large series have addressed this issue with differing results. Schwartz *et al*. reported a temporal benefit with regards to blood loss in patients with renal masses greater than 10 cm. The series included 46% (29 of 63) of patients who had a tumor thrombus involving the renal vein or inferior vena cava (IVC). The authors recommended that the optimum delay after renal embolization is 24–48 h and an extended delay may be needed in patients with IVC thrombus [5]. However, data from the other series do not support the same conclusion. Subramanian *et al*. investigated patients undergoing radical nephrectomy and IVC thrombectomy and compared those who underwent preoperative renal embolization with patients who had not. The series included 225 patients

and reported no benefit with preoperative embolization in patients with a renal mass and an IVC thrombus [6].

Some of the perceived advantages of preoperative embolization include a reactive edema of tissue planes facilitating dissection and allowing early ligation of the renal vein, a decrease in intraoperative blood loss, and cytoreduction of the tumor thrombus volume. Several studies have examined intraoperative blood loss; however, they are difficult to compare. One study suggests a significant decrease in the volume that is transfused post embolization in patients with large hypervascular tumors [7]. Giuliani *et al*. reported a similar reduction in patients with T3/T4 disease [8]. No specific recommendations can be gleaned from these heterogeneous patient data; therefore, the course of action is still left to the clinician to determine. A dialogue between urologist and interventional radiologist is essential in determining the individual treatment plan that is appropriate for each specific clinical situation.

Selective renal embolization has played a major role in the treatment paradigm of AML (Figure 119.3). In a literature review by Nelson *et al*. of 76 patients with

AML [9], The original 4-cm rule prompting intervention proposed by Oesterling *et al*. [10] held true; however, there were several additional variables that should be taken into account when dealing with these patients: pregnancy plans, patient age, comorbidities, and ability for surveillance [9]. There was a 10% complication rate associated with embolization of AML (not including postinfarction syndrome) and the most common complication was abscess formation (5%); yet, in four of the six larger series, no complications were reported. Fourteen percent of patients required repeat embolization in the meta-analysis [9]; however, this carried little added morbidity for the patient.

Renal artery pseudoaneurysms and arteriovenous fistulas (AVFs) can occur secondary to biopsy, trauma, percutaneous stone extraction, partial nephrectomy, and any other processes that disrupt renal parenchyma. Hematuria can be the presenting symptom if the pseudoaneurysm/AVF is in communication with the collecting system. The incidence in the open partial nephrectomy series from the Cleveland Clinic was 3 of 698 (0.43%) [11] compared to 6 of 345 (1.7%) in the laparoscopic partial nephrectomy (LPN) series from the same institution [12]; obviously, both incidences are very low. Prompt recognition and treatment are crucial to successful management. The diagnosis can be confirmed by CT scan of the abdomen and pelvis with and without contrast. The pseudoaneurysm appears as a focal high attenuation lesion on CT scan [11]. An AVF is characterized by early filling of the venous system on angiography (Figure 119.4). Renal angiography is still the gold standard for diagnosis and therapeutic modality and, based on the degree of suspicion, most patients undergo angiography without prior abdominal imaging (CT scan). Renal surgery is a form of controlled trauma; the use of conservative management as well as embolization in the treatment of renal trauma has been supported by data from the University of California, San Francisco General Hospital [13]. Conservative management or embolization was successful in managing patients with grades I–IV renal trauma, but unfortunately embolization failed in all patients with grade V renal trauma [13].

Figure 119.4 Post percutaneous stone extraction arteriovenous fistula (arrow).

Renal embolization is not without complications. The most common complication is postinfarction syndrome, which occurs 24–48 h after the procedure. It can be associated with nausea, vomiting, fever, flank pain, and mild leukocytosis. This occurred in 85% of patients evaluated by Nelson *et al*. [9]. The yield of blood and urine cultures is low in this situation. Management consists of antipyretics and analgesics for the associated pain. In extremely rare cases, tumor fragments have embolized [5].

Technique

Arterial access

The common femoral artery (CFA) is the most common site utilized for renal arterial access. The CFA path runs over the medial aspect of the femoral head (Figure 119.5). This area is important because the femoral head provides the posterior surface on which the physician can apply direct pressure after access has been discontinued, in order to achieve hemostasis. Alternatively, there are several vascular closure systems on the market that can expedite hemostasis, such as the Angioseal device (St Jude Medical, St Paul, MN, USA) and Starclose (Abbott Vascular, Chicago, IL, USA). The Angioseal device uses a vascular plug to maintain hemostasis, unlike Starclose, which utilizes a vascular clip.

First, a hollow-core, single-wall arterial puncture needle, such as a 19G Potts needle (Remington Medical Inc, Alpharetta, GA, USA) or a 21G Micro-puncture needle (Bard Inc, Murray Hill, NJ, USA), is used to access the CFA, typically entering at a 45° angle (Figure 119.6). The needle is then exchanged for a 6F sheath (Cordis Corp, Miami Lakes, FL, USA) over a 0.035-inch J-tipped wire (Cook Inc, Bloomington, IN, USA).

Angiography and catheters

Using the 0.035-inch wire, a 4 or 5F SOS Omni catheter (Angiodynamics, Queensbury, NY, USA) or a Cobra catheter 65 cm (Angiodynamics) is then placed within the origin of the renal artery. A small amount of iohexal contrast (Omnipaque™; GE Healthcare, Waukesha, WI,

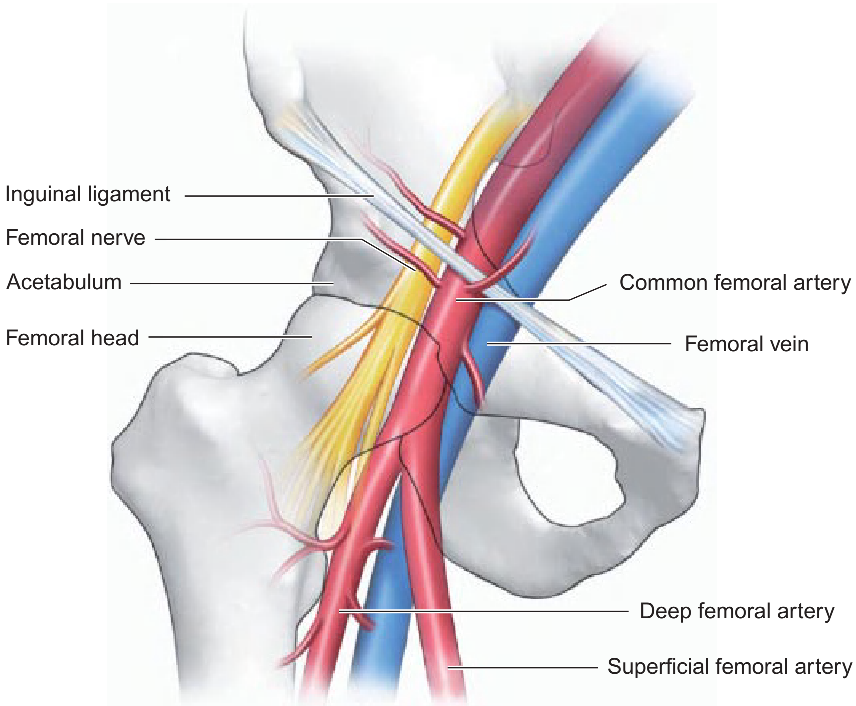

Figure 119.5 Course of the common femoral artery as it travels anterior to the medial aspect of the femoral head prior to its bifurcation into the deep femoral artery and superficial femoral artery.

USA) is injected through the catheter. Digital subtraction angiography (DSA) is performed to minimize the amount of contrast and radiation that the patient receives [14].

Identification of acute bleeding site

Renal arterial anatomy is delineated, and any source(s) of hemorrhage is identified. Common angiographic findings of hemorrhage include AVF, pseudoaneurysms, blind-ending vessels or active extravasations of contrast. AVFs are characterized by early filling of the venous system during arteriography. Pseudoaneurysms are saccular dilations of the arterial branches (Figure 119.7). Finally, lacerated segmental arteries are identified by contrast extravasation from a bluntly ended arterial branch (Figure 119.8).

Once the source of hemorrhage has been identified or still has not been elicited, the diagnostic catheter, or microcatheter, can be advanced and DSA can be repeated as needed. If no obvious source of bleeding is elicited on initial angiography, then we catheterize each of the segmental arteries, specifically arteries near the area of surgery (percutaneous stone extraction tract or partial nephrectomy renorrhaphy sites). An 2.8F microcatheter, 130 cm (Progreat microcatheter; Terumo, Tokyo, Japan) is then utilized through the larger diagnostic catheter, which is anchored in the main renal artery or segmental artery. This allows further investigation more distally into the third- or fourth-order arterial branches towards the origin of the bleeding vessel. A 0.018-inch micro guidewire, such as the Gold Tip glidewire (Terumo) or the Fathom Steerable guidewire (Boston Scientific, Natick, MA, USA) is used to probe and manipulate the catheter into the distal vessels.

Embolization

Using the findings on angiography, the physician needs to take into account the goal of embolization. If a tumor is to be embolized prior to nephrectomy or partial nephrectomy [15], then the entire tumor circulation needs to be occluded, in contrast to a postoperative patient presenting with bleeding from the surgical site. The most common agents for tumor embolization are liquids (99% ethanol), PolyVinyl Alcohol PVA (Contour; Boston Scientific) or Embospheres (BioSphere Medical, Rockland, MA, USA) can be utilized. These agents allow for distal progression and complete obstruction of the tumor's microcirculation. This is in contrast to occluding one specific bleeding vessel, for which glue or coils can be employed [16].

Microcoils such as the AZUR (Terumo) and Interlock (Boston Scientific) are currently the most common embolic devices utilized for renal embolization performed for a distinct arterial bleeding source (Figure 119.9).

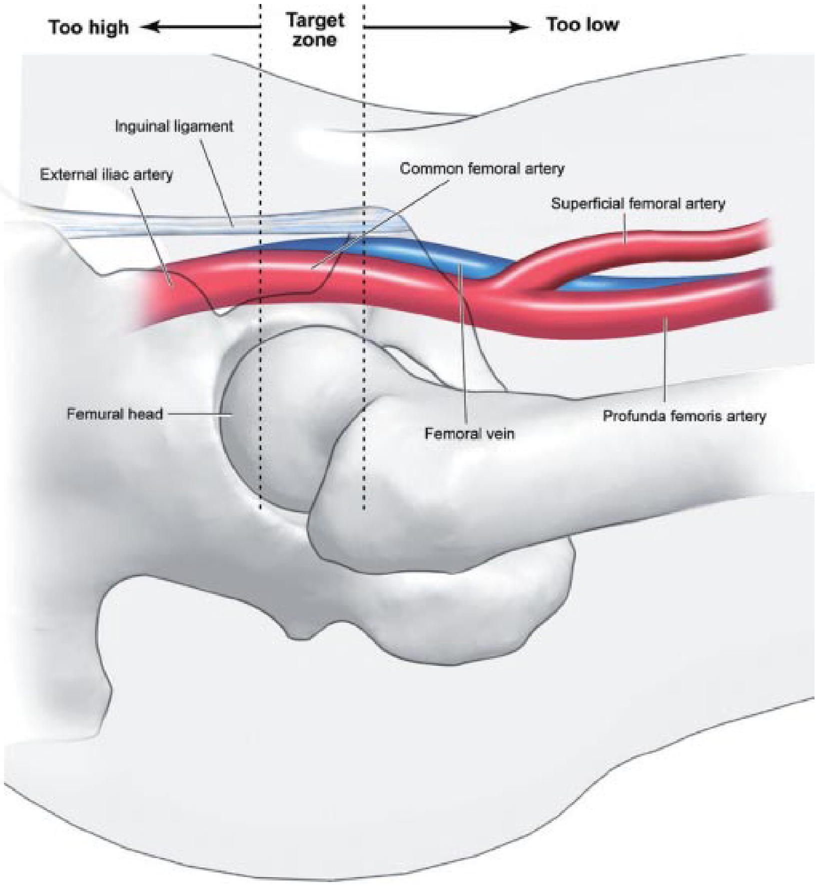

Figure 119.6 Suggested target zone for arterial puncture inferior to the inguinal ligament, above the superficial femoral artery–deep femoral arterial bifurcation and anterior to the femoral head.

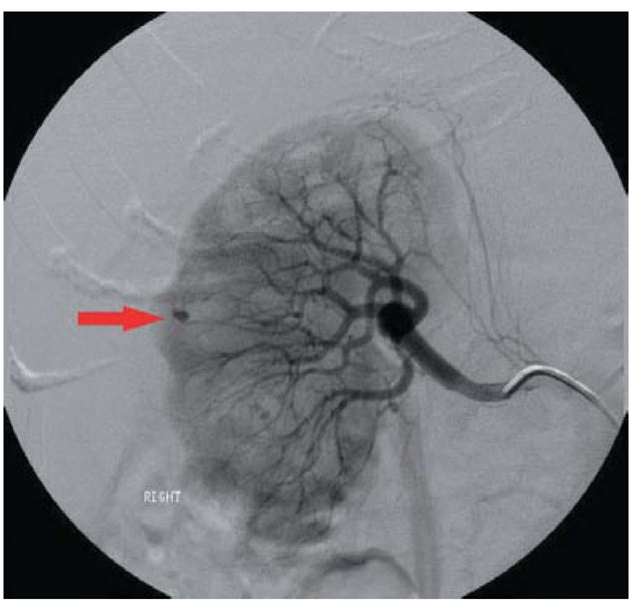

Figure 119.7 Pseudoaneurysm (arrow) observed on renal angiography.

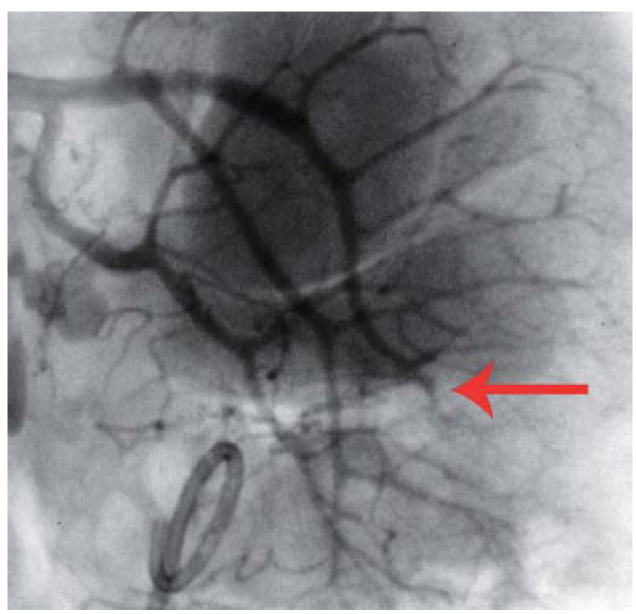

Figure 119.8 Blind ending vessel (arrow) on renal angiography following percutaneous stone extraction.

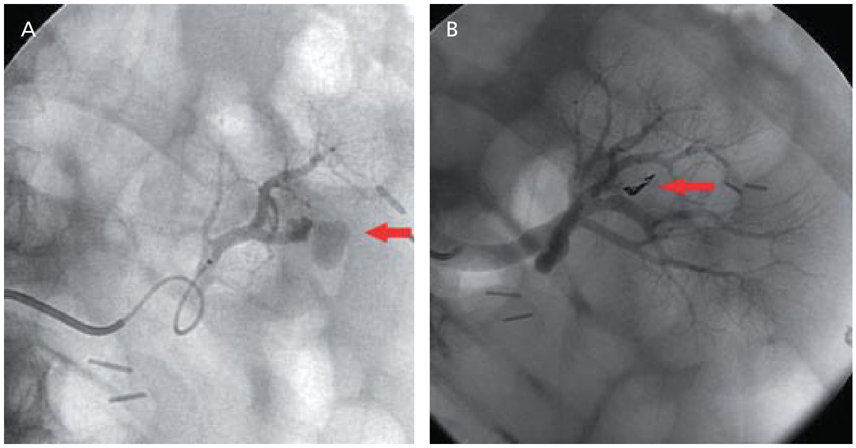

Figure 119.9 Pseudoaneurysm (arrow) (A) post partial nephrectomy and (B) post coil embolization.

Once hemostasis has been obtained by embolization, completion angiography is performed through the microcatheter as well as the diagnostic catheter to document effective embolization and assess the percentage loss of renal parenchyma.

Bladder angiography and embolization

Hemorrhagic cystitis is a common urologic problem with numerous causes. Pelvic radiation, infectious diseases (bacterial/viral), systemic diseases (rheumatoid arthritis, Crohn disease, amyloidosis), chemical cystitis (cyclophosmphamide, other alkylating agents), and medications (penicillin derivatives) have all been implicated as causes of hemorrhagic cystitis [17]. The treatment of the resultant hematuria and possible hemorrhage is directed individually at the primary etiology. Probably the most common cause of hemorrhagic cystitis is associated with a bacterial/viral infection; this is usually underreported because it is easily treated with appropriate medications and is self-limiting.

In patients with more severe hemorrhagic cystitis, several factors need to be addressed. First, it is important to understand the etiology of the hemorrhagic cystitis. For example, radiation cystitis is secondary to obliterative endarteritis of vessels while infectious causes lead to mucosal inflammation and bleeding. The additional treatment options are very different if conservative management strategies fail in these two patient groups.

Several treatments and strategies can be employed for hemorrhagic cystitis. In 1974, Hald and Mygind first reported the use of muscle fragments to emobolize a unilateral hypogastric artery in order to control severe bladder hemorrhage [18]. Since then, there has been significant progress in techniques and equipment. The goal is always to preserve as much functioning organ tissue as possible and to avoid nontarget embolization. Embolization has been employed as an adjunct to the normal treatment paradigm after all other treatments have failed. The indications for embolization have included refractory hematuria secondary to viral infection, cyclophosphamide, bladder/prostate malignancies, amyloidosis, and radiation cystitis [17].

Prostate angiography and embolization

Hematuria is a well-documented symptom of prostatic disease (BPH or cancer) and lead to significant morbidity. The incidences of hematuria associated with BPH, prostate cancer, and external beam radiation of the prostate are 20%, 0.7%, and up to 0.5%, respectively [19]. The majority of patients with hematuria can be easily diagnosed and treated noninvasively. Hematuria is treated initially using a functional approach, directly addressing the hematuria with Foley catheter drainage, clot evacuation, irrigations, and transurethral fulguration/resection of the bleeding tissue. Also, depending on the etiology, a biochemical approach can be used, which could consist of 5-alpha-reductase inhibitors or androgen deprivation.

In the extreme situation of a patient with refractory hematuria, some authors have advocated open surgical and/or endoscopic management. One option for patients with refractory prostatic hematuria is selective arterial prostatic embolization (SAPE) (Figure 119.10) [20]. We treated eight patients with refractory hematuria and 100% had cessation of the life-threatening hematuria; however, this procedure is not without complications. One patient with T4 prostate cancer invading the rectum developed a rectoprostatic urethral fistula after embolization [20]. We believe the risk of fistula is extremely low, except in this unique situation in which

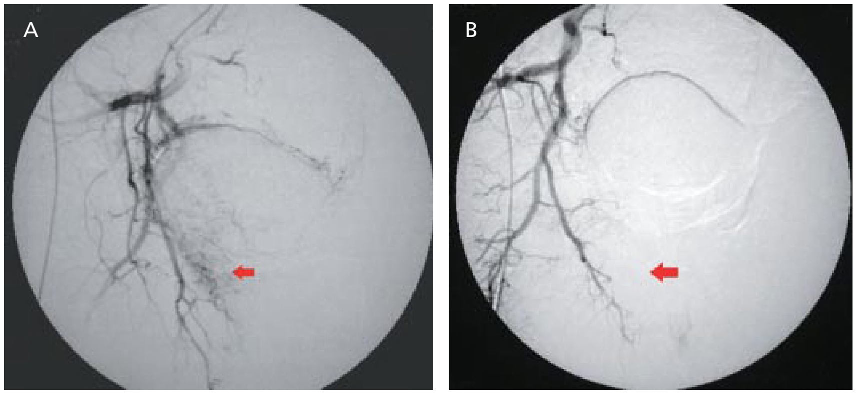

Figure 119.10 (A) Selective angiography of internal iliac artery demonstrating neovascularity (arrow). (B) Follow-up angiography demonstrates pruning of neovascularity of the prostate (arrow).

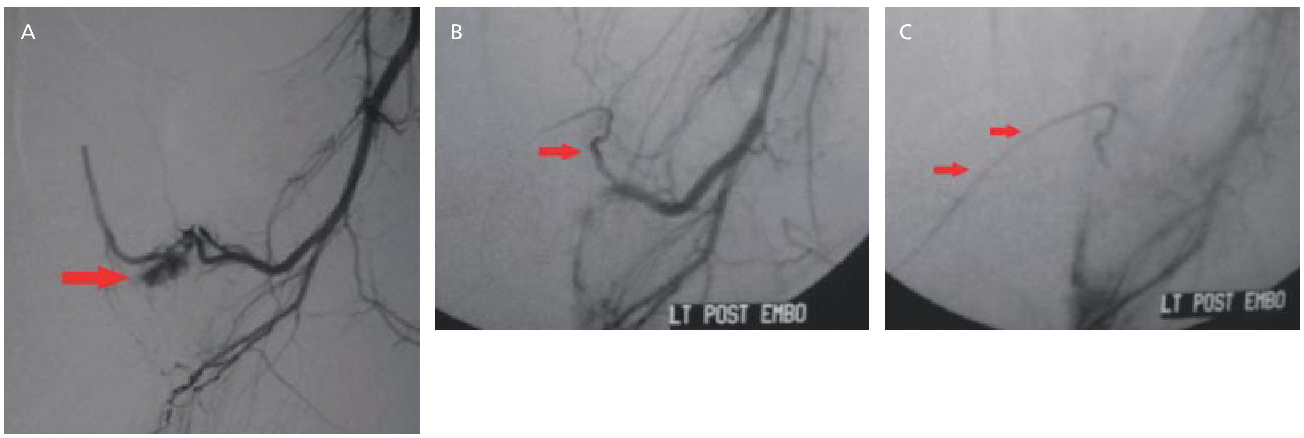

Figure 119.11 (A) Selective angiogram of the internal pudendal artery with an arteriovenous fistula into the corpora (arrow). (C) Note the distal filling of the penile artery (arrows).

the prostate cancer had destroyed the natural planes and rectal wall.

Recently, the indications for SAPE have been expanded by some authors to treat BPH [21–23]. There has also been some preclinical work in a hormone-induced BPH canine model [24]. The approach used differs between the small case series, depending on the embolization agent used and the type of postprocedural follow-up. These researchers' data do appear to be the groundwork for a new emerging treatment in BPH. They further reinforce the need for cooperation between urologist and interventional radiologist to better understand the treatment options for these patients. Selective embolization has also been employed as an alternative to returning to the operating room after radical prostatectomy. Several authors have reported on the use of selective embolization to control bleeding after radical prostatectomy or transurethral resection of the prostate [25–28].

Penile embolization [nonischemic (high-flow) priapism]

Priapism can be divided into two categories, the low-flow or ischemic variety, and the less common high-flow (nonischemic) variety. The latter has typically been treated with observation and embolization. High-flow priapism can be secondary to trauma or occur post treatment of ischemic priapism [29]. The American Urological Association (AUA) guidelines recommend observation for the initial treatment of high-flow priapism: 62% of patients had resolution and 33% patients complained of erectile dysfunction [30].

If observation fails or the patient requests definitive treatment of nonischemic priapism, selective embolization is the treatment of choice. The goal of embolization is to close the AVF, which is the cause of the high-flow priapism (Figure 119.11) [31]. It is important to consider which embolic agent to utilize because data reveal a

difference in degree of postoperative erectile dysfunction when comparing permanent versus temporary embolic agents (39% vs 5%, respectively) [30]. The resolution rates are similar after embolization, for permanent and nonpermanent embolic agents (78% vs 74%, respectively). Surgical management is a last-resort option which carries a lower success rate (63%) and a higher rate of erectile dysfunction (50%) [30].

Varicoceles

Varicoceles are present in 15% of male adolescents, with a very strong left-sided predominance [32]. The evaluation of men presenting with subfertility reveals a varicocele as the etiology in one in three patients [33]. Current indications for intervention include infertility in the adult male, pain, and asymmetric testicular growth (>2 mL or 20% volume difference) in the adolescent [34]. Kass *et al*. reported that 80% of the adolescent patient population after varicocele treatment may exhibit catch-up growth [35].

The direct benefit of treating varicocele for subfertility is difficult to assess due to the lack of randomized controlled trials. Using the data available, there is an approximate 15% increase in fertility rates when compared to control groups [36]. Argarwal *et al*. performed a meta-analysis and reported improvement in semen parameters in men treated for a palpable varicocele and abnormal semen analysis [37].

Several different approaches can be employed in the treatment of varicoceles, including mass ligation or a microsurgical approach to embolization (Figure 119.12). The failure rates need to be considered; as low as 1% was reported for the microsurgical approach [38] and 5.9% for embolization (208 of 221) [39]. There is also a significant difference in the incidence of hydrocele with each technique; it is much higher in patients treated using the Palomo technique compared to embolization (8.2% vs 0%, respectively [38]. There is still no clear-cut data regarding the best technique as these are limited and authors have treated heterogeneous populations of men with varying degrees of subfertility.

Pelvic congestion syndrome

Pelvic congestion syndrome is thought to be secondary to venous valve incompetence and dilation of periovarian/periuterine varices (Figure 119.13), which is often exacerbated during pregnancy when ovarian blood flow can be increased to 60 times that of normal [40]. Investigators have evaluated the use of sclerotherapy/embolization to treat these patients, which is analogous in theory to the treatment of varicoceles but requires the use of sclerotherapy. This is due to the complex network of plexi allowing for communication between the bilateral ovarian and internal iliac venous systems. Sclerotherapy is usually performed with 3% sodium tetradecyl sulfate foam (Angiodynamics).

These patients have been treated with a medical approach aimed at decreasing venous pooling by utilizing medroxyprogesterone acetate to induce venous contraction [41]. Venous embolization has shown a complete or partial treatment success in 73.7% (14 of 19 patients) [42]. Several other investigators have confirmed similar findings in the treatment of pelvic congestion syndrome [43, 44].

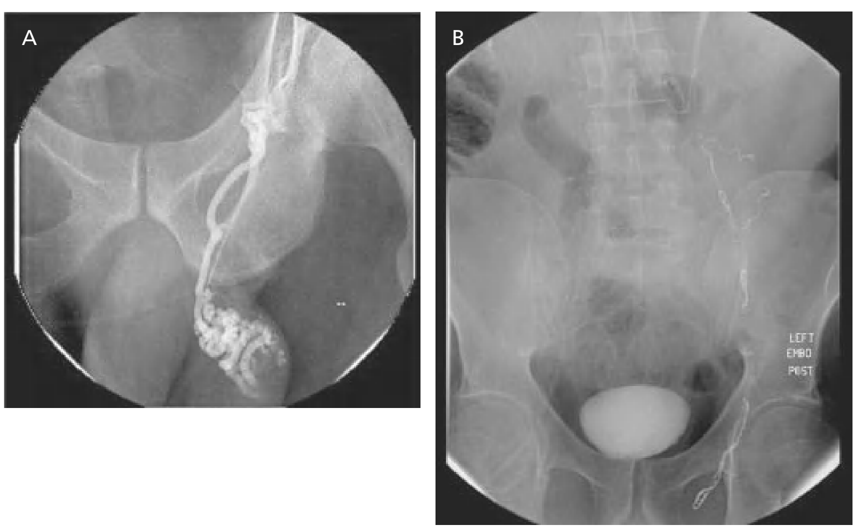

Figure 119.12 (A) Gonadal venography demonstrating a left-side varicocele. (B) Post embolization. The goal is to embolize at multiple levels: inguinal canal, inferior and superior boarder of sacrum, and just prior to the insertion of the gonadal vein into the renal vein (left side) or vena cava (right).

Conclusions

Over the past 50 years, urologists and interventionalists have worked together to treat urologic patients. Minimally invasive therapies have led a revolution in the way we take care of our patients. Angiography and embolization have taken their place as well within the urologic armamentarium. As collaborative efforts continue within our disciplines, the role of angiography in urology will continue to expand.

Introduction

Benign prostatic hyperplasia (BPH) is an age-dependent pathoanatomic condition with an initial histopathologic development after 40 years of age, and prevalence rates of approximately 50% and 90% by 60 and 85 years of age, respectively. Cell proliferation associated with BPH is comprised of both epithelial and stromal elements and may result in benign prostatic enlargement (BPE), which can cause bladder outlet obstruction (BOO) and a constellation of lower urinary tract symptoms (LUTS) that are commonly classified as "obstructive voiding" or "irritative storage."

In most instances, the patient has more than one complaint. It has generally been assumed that obstructive symptoms are caused by prostatic obstruction and that irritative symptoms are caused by inflammation or detrusor overactivity. Despite the logic implied, most clinical studies that document the relationship between symptoms and underlying pathophysiology have established no such correlation.

Although existing medical and surgical interventions attempt to reduce the obstructive component to provide symptomatic relief, the association between BPH, benign prostatic obstruction (BPO) and BOO is complex. For example, it is unclear whether urethral obstruction is the primary mechanism by which BPH causes symptoms. Nor is it known whether the relief of the obstruction is a prerequisite to successful treatment of symptoms. Likewise, the relationship between symptoms and commonly used indices of prostatism, such as uroflow and postvoid residual urine, is unknown.

Recent evidence suggests that the etiology of prostatic symptoms is multifactorial involving (1) prostatic urethral obstruction, (2) impaired detrusor contractility, (3) detrusor overactivity, and (4) urgency [1]. The best method to definitively diagnose BOO is the detrusor pressure–uroflow flow study (PFS), but there is much more to be obtained from urodynamics than simply diagnosing obstruction.

This chapter will describe existing urodynamic techniques used in the diagnosis of BPH, as well as review the role of urodynamics in the evaluation of LUTS and urinary incontinence.

Background

LUTS are generally categorized into storage and emptying symptoms. Storage symptoms include urinary frequency, urgency, urge incontinence, nocturia, and bladder/urethral pain during filling. Emptying symptoms comprise of hesitancy, straining to void, weak force of stream, a feeling of incomplete bladder emptying, and urinary retention. In men, BOO resulting from BPH is only one of many causes of LUTS. Others causes include idiopathic and neurogenic detrusor overactivity, urgency impaired detrusor contractility, and polyuria. It is not possible to make the diagnosis of BOO on symptom

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

assessment alone. In patients with LUTS, urodynamic evidence of BOO exists in only 50–66% of patients [2–5]. A number of studies have demonstrated a lack of correlation between symptoms, American Urological Association (AUA) symptom score or the Danish Prostate Symptom Score and any urodynamic data in patients with suspected BPH and BOO [6–9].

Determining the urodynamic abnormalities responsible for LUTS is important so that treatment can be directed at the underlying pathophysiology. Currently, the majority of medical and surgical interventions target the reduction or elimination of prostatic obstruction, yet only about two-thirds of men are actually obstructed. In fact, therapies should be specific for detrusor overactivity, urgency, and impaired detrusor contractility, and urodynamics are necessary to make the distinctions between these entities. The most definitive method of diagnosing obstruction and impaired detrusor contractility is the detrusor pressure–uroflow study, whereas only cystometry is necessary to distinguish urgency and detrusor overactivity. Although uroflow, postvoid residual urine volumes (PVR), symptom analysis, and questionnaires all play a role in evaluating men with suspected BOO, only urodynamics can make the necessary distinctions to allow therapy to be tailored to the underlying condition.

Table 120.1 Relevant data before and after treatment.

- Structured micturition history
- Global assessment score, such as the AUA or the Overactive Bladder Symptoms Score
- Physical examination including:
  - General examination
  - Brief screening neurologic examination (to discriminate normal, paraplegic, quadriplegic, hemiplegic, dementia, etc.)
  - Focused neurologic examination (perianal sensation, anal sphincter tone and control, and bulbocavernosus reflex)
  - Prostate examination
- A micturition diary including:
  - Time of micturition
  - Description of symptoms
  - Voided volume
- Uroflow (Q) and postvoid residual determination (PVR):
  - Urodynamic parameters: the following parameters permit patients to be objectively classified as having prostatic obstruction or impaired contractility:
    i. Maximum uroflow (Qmax)
    ii. Detrusor pressure at maximum flow (pdet@Qmax)
  - Other useful urodynamic parameters include:
    i. Presence or absence of detrusor overactivity
    ii. Bladder sensation and ability to abort involuntary detrusor contractions
    iii. Bladder capacity
    iv. Voided volume

Defining and quantifying symptoms

To evaluate the outcomes in any meaningful way, it is necessary to tabulate relevant data before and after treatment (Table 120.1).

Preparation for a urodynamic study

The main purpose of urodynamic evaluation is to document the underlying cause of the patient's complaints and to correlate symptoms with urodynamic findings. From a clinical standpoint, the purpose of urodynamic testing is to measure and record various physiologic variables while the patient is experiencing those symptoms that constitute his usual complaints. Thus, in this context urodynamics should be considered to be a provocative test of vesicourethral function, and it is the responsibility of the examiner to insure that the patient's symptoms are reproduced during the study. To this end, it is important that the examiner has all relevant clinical information prior to and during the urodynamic study. For example, the examiner should have results of fairly extensive evaluation including (1) a focused history and physical examination, (2) urinalysis ± culture, (3) a 24-h bladder diary, (4) a 24-h pad test (for patients with incontinence), (5) uroflow, and (6) PVR.

Further, in order to interpret urodynamic studies more accurately, the following information should be available to the examiner before the start of the study:

a. What symptoms are you trying to reproduce?
2. What is the functional bladder capacity (maximum voided volume on the voiding diary)?
a. What is the PVR?
3. What is the uroflow? (is there likelihood of either urethral obstruction or impaired detrusor contractility?)
a. Is there a neurologic disorder that could cause neurogenic bladder?

The multitude of urodynamic techniques and parameters may confound the practicing physician, but in principle there are only five: cystometry, uroflow, leak point pressure, sphincter electromyography, and radiographic visualization of the lower urinary tract. Each technique may be performed alone or synchronously with one another. When done synchronously, the tests are called multichannel urodynamics and when performed with fluoroscopic visualization of the lower urinary tract, videourodynamics. In the following section, use of each urodynamic technique in the evaluation of lower urinary tract symptoms will be explained.

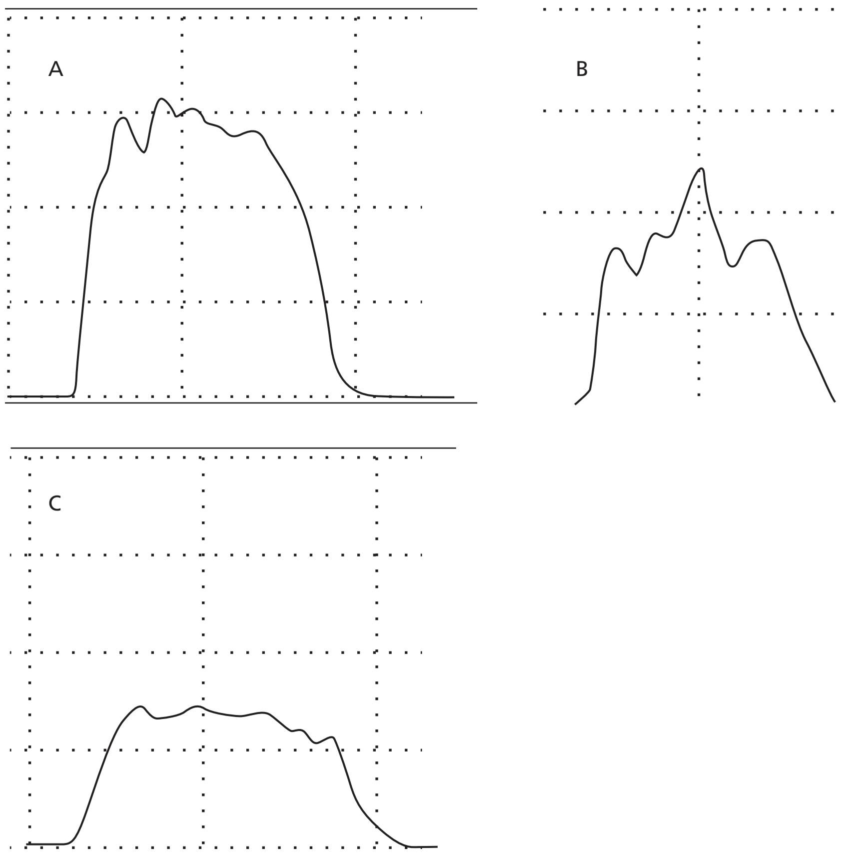

Figure 120.1 (A–D) Normal continuous uroflows. (A) Normal uroflow in a 52-year-old man. The pattern is continuous and the curve is very slightly fluctuating. Maximum flow (Qmax) = 31 mL/s; average flow rate (Qave) = 22 mL/s; voided volume = 269 mL; postvoid residual volume (PVR) = 0 mL. (B) Normal uroflow in a 53-year-old man. The pattern is continuous and the curve is fluctuating. Qmax = 24 mL/s; Qave = 13 mL/s; voided volume =190 mL; PVR = 0 mL. (C) Normal uroflow in a 59-year-old man. The pattern is continuous and the curve is slightly fluctuating. Qmax = 15 mL/s; Qave = 10 mL/s; voided volume = 200 mL; PVR = 10 mL.

Evaluation of lower urinary tract symptoms

Voiding symptoms with uroflowmetry

In general, voiding symptoms have one or more of three basic underlying etiologies: BOO, impaired detrusor contractility, and/or detrusor overactivity. BOO is characterized by a detrusor contraction of adequate magnitude (pressure) and duration, and a diminished flow. Impaired contractility is characterized by a weak or poorly sustained detrusor contraction and a low flow.

Uroflowmetry is a simple, objective, and noninvasive method to evaluate LUTS. Uroflowmetry is not used to evaluate filling symptoms. It should be performed in a private setting with the patient sitting or standing to reproduce normal voiding patterns. From simple uroflowmetry maximum urinary flow (Qmax), flow pattern, voided volume, and shape of curve can be obtained. After voiding, the PVR is recorded with ultrasound or catheterization if invasive urodynamics are to follow.

Uroflowmetry is best performed when the patient experiences a normal desire to void. A minimum urine volume of 150 mL provides an accurate study [10]. Existing nomograms provide values with age- and volume-adjusted flow rate [6, 7, 11]. A Qmax of greater than 15 mL/s is considered normal, and approximately 95% of patients with this parameter will not be obstructed [12]. A Qmax of less than 10 mL/s is considered abnormal, and of 10–15 mL/s is equivocal [12]. A variety of normal uroflowmetry with normal curves and parameters is shown in Figure 120.1.

Uroflowmetry is unable to distinguish obstructed from unobstructed patients [13]. An equivocal uroflow may be seen in patients with significant obstruction and an abnormal flow may be seen in a patient with poor detrusor function. It is obvious that BOO is associated with a low urinary flow rate, but it may also be associated with impaired contractility. In patients who are obstructed, uroflowmetry cannot differentiate types of urethral obstruction (BPH, urethral stricture, etc.). Figure 120.2 displays two similar abnormal

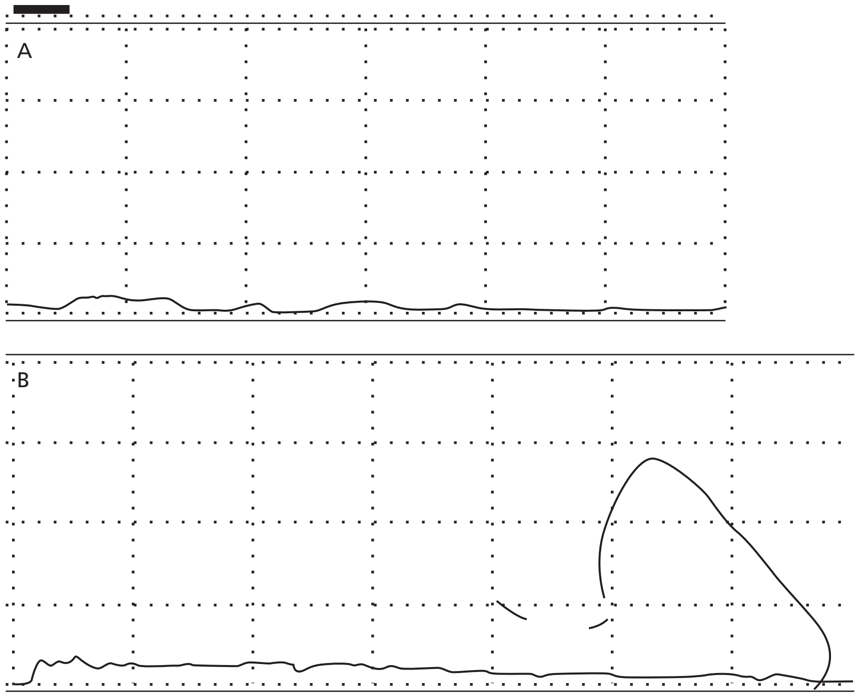

Figure 120.2 (A) Low flow due to impaired detrusor contractility. Maximum flow (Qmax) = 2 mL/s; average flow (Qave) = 2 mL/s; voided volume = 58 mL; postvoid residual volume (PVR) = 120 mL. (B) Low flow due to urethral obstruction. Qmax = 3 mL/s; Qave = 2 mL/s; voided volume = 149 mL; PVR = 212 mL.

uroflowmetry patterns despite their having different etiologies.

Despite these limitations, uroflowmetry remains a useful initial evaluation of men with LUTS. The AUA guidelines (2003) recommend uroflowmetry as an optional test in men with moderate/severe symptoms [14]. However, the European Association of Urology Guidelines on BPH recommend uroflowmetry in the assessment and diagnostic work-up of men with LUTS and is considered mandatory prior to surgical intervention [15].We recommend uroflow for all men with LUTS.

Uroflowmetry remains an important tool in evaluating efficacy of medical and surgical treatments. It is a constant and powerful parameter utilized in reporting outcomes.

Filling symptoms with cystometry

Filling symptoms may be caused by detrusor overactivity, urgency, low bladder compliance, reduced bladder capacity, or polyuria. It is imperative to exclude other underlying causes of filling symptoms, such as urinary tract infection, bladder and prostate cancer, urolithiasis, and neurogenic bladders, prior to urodynamic testing. Polyuria can be caused by excessive fluid intake, diabetes mellitus, diabetes insipidus, and other less common conditions. Nocturia may be the result of abnormal drinking patterns, a reversal of the normal diurnal antidiuretic hormone cycle, congestive heart failure, venous insufficiency, sleep apnea, lower extremity edema, diabetes mellitus, or hypertension.

Filling cystometry is the only method that can document detrusor overactivity, and low bladder compliance; however, it is not useful as a standalone procedure in men with LUTS. Currently, the AUA guidelines recommend that cystometry be done as part of the PFS. In men experiencing LUTS, up to two-thirds may be found to have detrusor overactivity. Despite poor physiologic explanation, resolution of detrusor overactivity can be expected in 50–70% of patients after outlet reduction [16, 17] Figure 120.3 demonstrates an idealized cystometrogram as well as an actual cystometrogram from a patient: note that without abdominal pressure tracings, the cause of vesical pressure increase cannot be determined accurately.

Multichannel urodynamics and videourodynamics

The simultaneous measurement and display of multiple urodynamic parameters is the most precise diagnostic tool for evaluating abnormalities of micturition. As described earlier, the addition of radiographic visualization of the lower urinary tract with multichannel urodynamics is termed videourodynamics. In these studies, radiographic contrast is used as the infusant

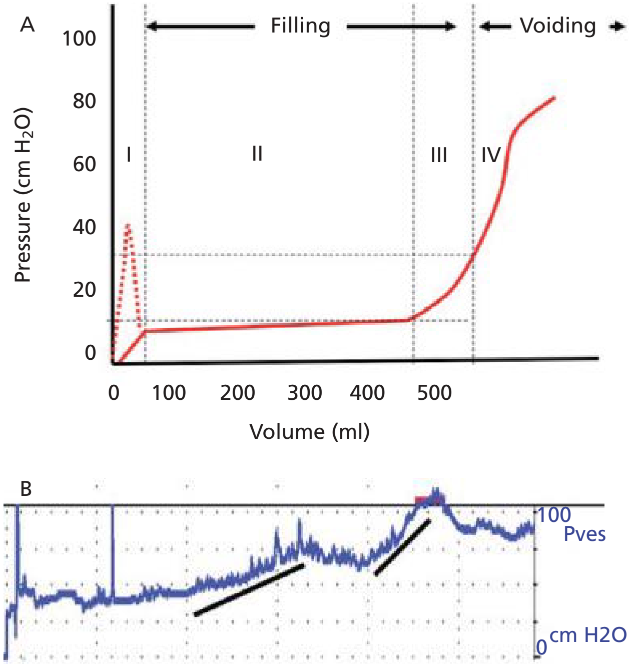

Figure 120.3 (A) An idealized cystometrogram. The dashed red line in phase I is seen only with very rapid filling, such as that attained when CO_2 is used. It is attributed to the viscoelastic properties of the bladder wall. Note that bladder compliance changes at different bladder volumes. Bladder compliance during the tonus limb (phase II) = 400 mL/10 cmH_2O = 40 mL/cmH_2O; at the end of phase III (500 mL) = 100 mL/20 cmH_2O = 5 mL/cmH_2O. (B) This cystometrogram demonstrates two steep rises in vesical pressure (pves). The black lines parallel the pressure rises. Without further information, it is not possible to determine whether these are due to straining, detrusor contractions or low bladder compliance.

for cystometry and other urodynamic parameters, including abdominal pressure, uroflow and sphincter electromyography, are recorded as well. By measuring multiple urodynamic variables, a better insight into the underlying pathophysiology is gained, as well a better appreciation of their interrelationships and of artifacts. The International Continence Society has recommended standards for the performance of these studies [18, 19].

The main purpose of urodynamic evaluation is to recreate the patient's complaints and to correlate symptoms to the urodynamic findings. Thus, it is essential to understand the nature of a patient's complaints and to use the urodynamic evaluation as a provocative test to mimic those symptoms, as alluded to above. During the interactive process, the examiner should document whether or not the patient's symptoms are reproduced and, if they are, the underlying cause should be clearly understood before completion of the study.

Urodynamic technique

A uroflow should be obtained prior to the urodynamic evaluation. Then, a 7F double-lumen bladder and rectal catheter are passed into the bladder and rectum to measure vesical and abdominal pressure, respectively, and PVR is measured via the urethral catheter. Pressure transducers are zeroed to atmospheric pressure at the level of the symphysis pubis. The patient should be asked to cough or Valsalva to insure proper reading of instruments on the computer display. Vesical pressure (pves) and abdominal pressure (pabd) are measured directly from the urethral and rectal catheters, respectively, and displayed on a computer screen. Detrusor pressure (pdet) is electronically calculated by subtracting pabd from pves and displayed on a third channel. Other channels display sphincter electromyelogram (EMG), infused bladder volume, filling rate, voided volume, and uroflow. For videourodynamics, fluoroscopic images are sampled periodically as well as at times of events such as urgency and micturition.

Evaluation of filling symptoms

During bladder filling, the presence or absence of detrusor overactivity is noted and bladder compliance recorded. If detrusor overactivity is documented, the patient's awareness, concern, and ability to contract the sphincter, abort the stream, and prevent incontinence are noted. These characteristics are used to classify the type of overactive bladder [20] (Figure 120.4).

Detrusor overactivity is seen in over 50% of patients with BPH, but its presence does not correlate with urethral obstruction [1, 21–23]. A patient with clinical BPH may have detrusor overactivity in the presence of prostatic obstruction. Even in the absence of prostatic obstruction, detrusor overactivity may cause obstructive symptoms. For example, a patient may develop involuntary bladder contraction at a relatively low bladder volume, which is perceived as an urge to void. The patient rushes to the bathroom, however, by this time the involuntary contraction has subsided and there is no longer an urge to void. Attempts to void by the patient with straining and pushing will be unsuccessful due to the small bladder volume. Thus, once it has been determined that there are overactive detrusor contractions, it is important to determine the degree of the patient's awareness, concern, and control.

Evaluation of voiding symptoms

BOO and urethral resistance are defined by PFS parameters. The BOO index (BOOI) is used to measure the degree of obstruction. It is calculated using the formula:

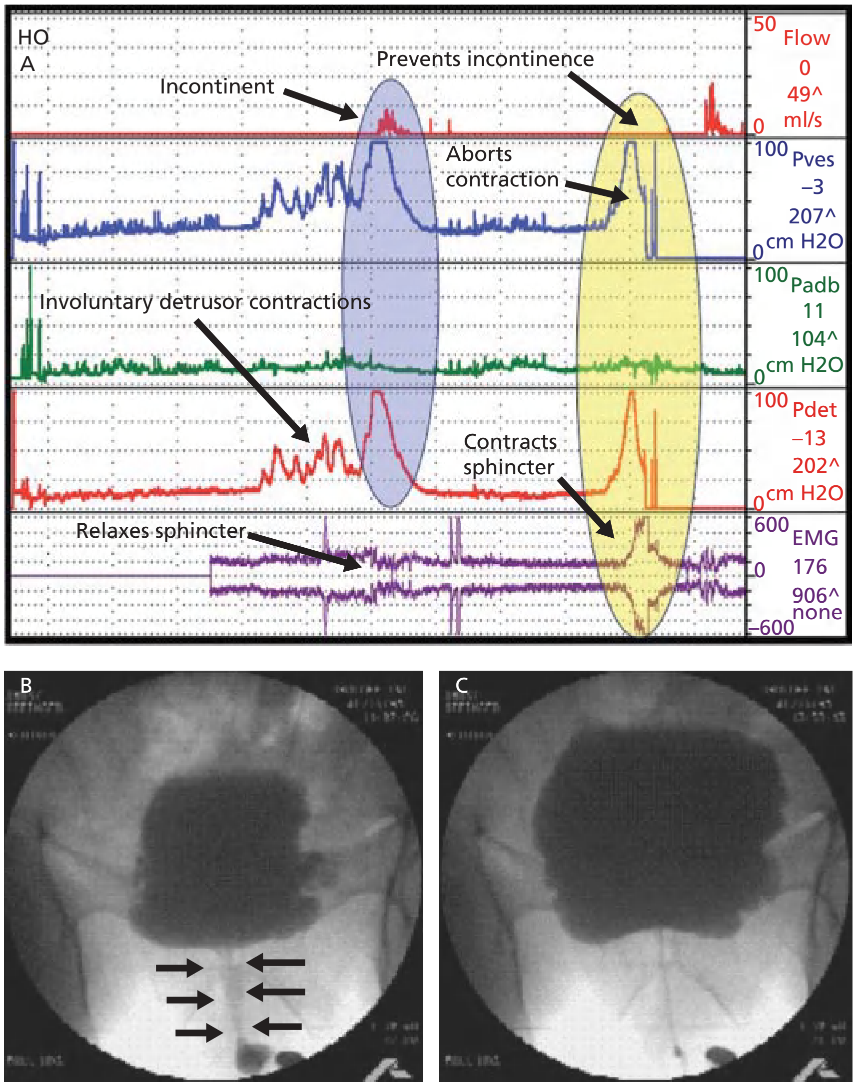

Figure 120.4 (A) Urodynamic tracing of a Type 2 overactive bladder and prostatic obstruction in a 53-year-old man with a 20-year history of refractory urgency, urge incontinence, and enuresis. During bladder filling the patient is instructed to neither void nor prevent micturition and to report his sensations to the examiner. There are a series of poorly sustained involuntary detrusor contractions (arrow) that he perceives as a severe urge to void, and then there is a sustained voiding contraction whence he relaxes his sphincter and voids (blue oval). Detrusor pressure at maximum flow (pdet@Qmax) = 100 cmH_2O; maximum flow (Qmax) = 8 mL/s (Schafer grade 5 obstruction). The bladder is filled again and there is another involuntary detrusor contraction. This time the patient is instructed to try to hold. He contracts his sphincter, obstructing the urethra, and the detrusor contraction subsides and he is not incontinent (yellow oval). (B) X-ray obtained at Qmax shows a narrowed and faintly visualized prostatic urethra (arrows) characteristic of prostatic obstruction. The bladder is trabeculated and there are several small and medium-sized bladder diverticula. (C) X-ray obtained as the patient contracts his sphincter to prevent incontinence (gray oval). The contrast would be expected to stop at the distal prostatic urethra, but since the patient has prostatic obstruction that narrows the proximal urethra, no contrast is seen in the urethra at all.

$$\text{BOOI} = \text{Pdet Qmax} - 2\text{Qmax}$$

where Pdet Qmax is the detrusor pressure at maximum flow. Men are classified as obstructed (BOOI > 40), equivocally obstructed (BOOI > 20 – <40), or unobstructed (BOOI < 20).

Multiple nomograms have been described to interpret PFS [12, 24, 25]. These plot detrusor pressure (at maximum flow) versus the maximum flow rate, and then divide results into unobstructed, obstructed, and equivocal categories. We prefer the Schaefer nomogram because it provides a simple six-point obstruction scale [18]: grade 0–1 is not obstructed; grade 2–3 is equivocal, and grade 4–6 is obstructed.

The urodynamic tracings, fluoroscopic images, and their application to a Schafer nomogram in Figure

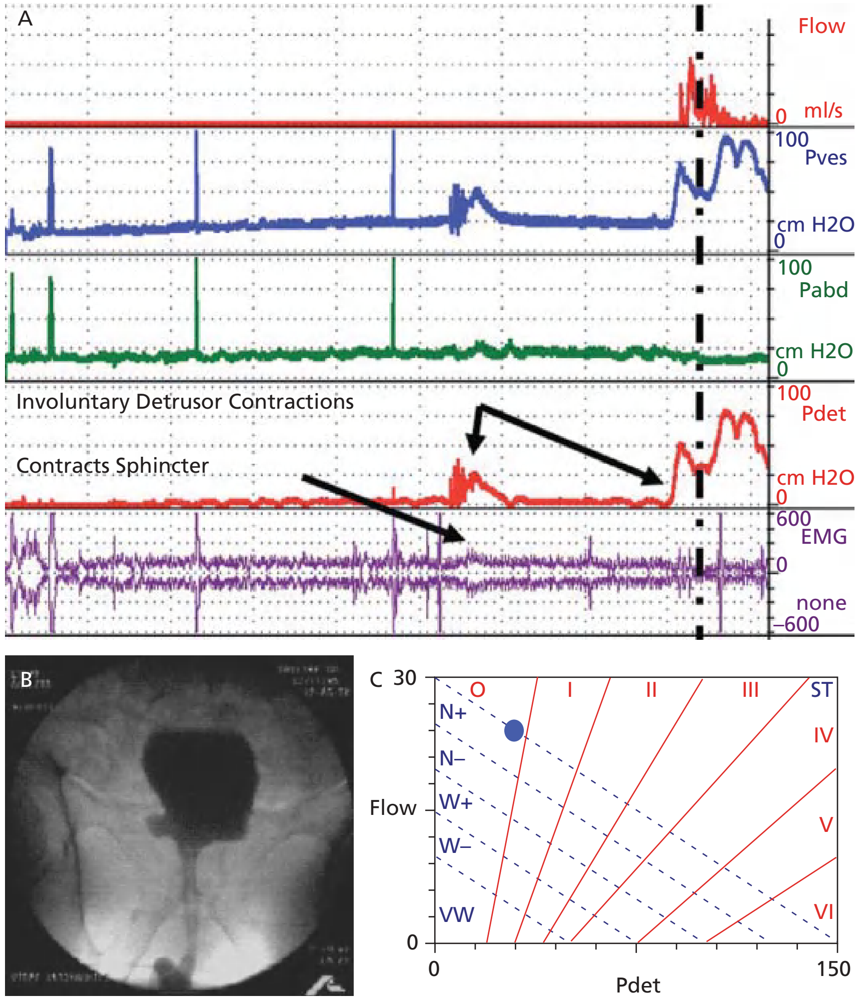

Figure 120.5 (A) Urodynamic tracing of a man with two involuntary detrusor contractions; the terminal one causes incontinence. However, there is no bladder outlet obstruction. Maximum flow (Qmax) = 17 mL/s; detrusor pressure at maximum flow (Pdet@Qmax) = 22 cmH_2O. (B) Voiding cystourethrogram showing a wide open urethra during maximum flow. (C) Schafer nomogram plotting Qmax versus pdet@Qmax, yielding grade 0 voiding with excellent (N+) detrusor contractility.

120.5–120.7 demonstrate the role of each element in the differentiation of LUTS symptoms.

The Schafer nomogram also incorporates bladder contractility in addition to an obstructive index. The slope of Schafer's contractility lines are obtained by the formula for bladder contractility index (BCI):

$$BCI = Pdet\,Qmax + 5Qmax$$

A BCI greater than 150 is considered to be a strong contraction, a BCI less than 100 is considered to be weak, and a BCI of 100–150 is considered to be normal [26, 27].

Cystoscopy

Urethrocystoscopy is recommended in evaluating men with suspected BPH with a history of microscopic or gross hematuria, prior lower urinary tract surgery, bladder cancer, and urethral stricture. It is not required in those patients who opt for medical therapy. AUA guidelines recommend use of urethrocystoscopy in those patients where the "endoscopic appearance of the prostate may guide the choice of therapy in patients who have already decided to proceed with an invasive approach" [14].

Urinary incontinence

Urinary incontinence occurs in about 5–10% of men with clinical BPH. Most patients have urge incontinence. Sphincteric incontinence in men with BPH does not occur unless the patient has a neurologic condition or has undergone prior surgery or radiation. By far the most common cause of sphincteric incontinence is radical prostatectomy for prostate cancer followed by transurethral prostatectomy, particularly after radiotherapy for

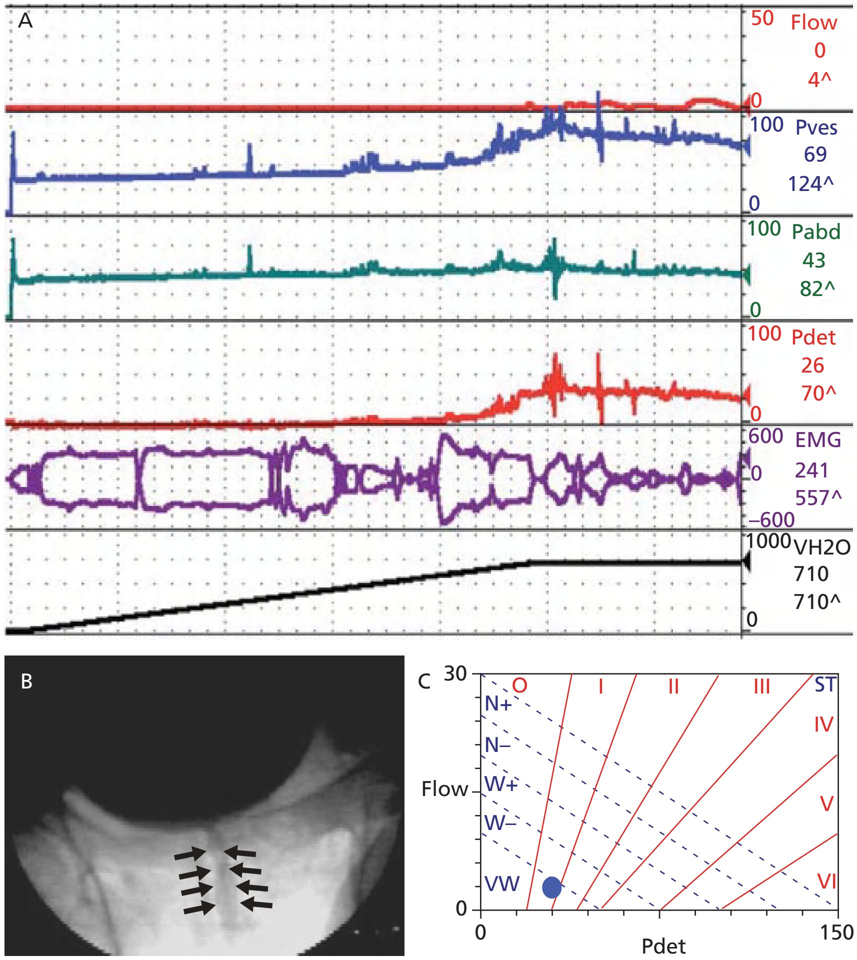

Figure 120.6 (A) Urodynamic study of impaired detrusor contractility (VW) in a 58-year-old man complaining of urinary frequency, urgency, occasional urge incontinence, hesitancy, and weak stream. First sensation of filling (FSF) = 272 mL; first desire = 491 mL; severe desire = 620 mL; bladder capacity = 710 mL; maximum flow (Qmax) = 6 mL/s; detrusor pressure at maximum flow (pdet@ Qmax) = 28 cmH_2O; maximum detrusor pressure (pdetmax) = 41 cmH_2O; bladder contractility index = 58. (B) X-ray obtained at Qmax shows a narrowed prostatic urethra (arrows). (C) Nomogram reveals unobstructed voiding (grade 1) with very weak detrusor contractility. Bladder contractility index = 58.

prostate cancer [28]. Less common causes are neurologic, including thoracolumbar neurologic lesions, such as spina bifida, multisystem atrophy (Shy–Drager syndrome), and after abdominoperineal resection of the rectum.

In the vast majority of patients after radical prostatectomy, incontinence is transitory, usually spontaneously subsiding in a matter of months, although it may take as long as 1 year for full recovery. Sphincteric incontinence that occurs in men who have undergone radiation (external beam or brachytherapy), on the other hand, often does not spontaneously remit. Rather, if incontinence improves, it is usually because of the development of a urethral stricture that begins a vicious cycle. Treatment of the stricture usually results in recurrent incontinence and treatment of the incontinence (sphincter prosthesis or male sling) is often complicated by the development of recurrent stricture [29, 30].

From a diagnostic standpoint, most patients who complain of a constant, dribbling, gravitational or stress-induced incontinence have sphincteric malfunction, and most who complain of urinary frequency, urgency, and urge incontinence have an overactive bladder/detrusor overactivity. However, there may be considerable overlap between these two conditions and both may coexist in the same patient. Sphincter malfunction is the commonest cause of postprostatectomy incontinence (PPI), accounting for about 95% of cases, but it may be accompanied by detrusor overactivity and/or low bladder compliance. As an isolated cause, detrusor overactivity causes about 5% of PPI [31–33].

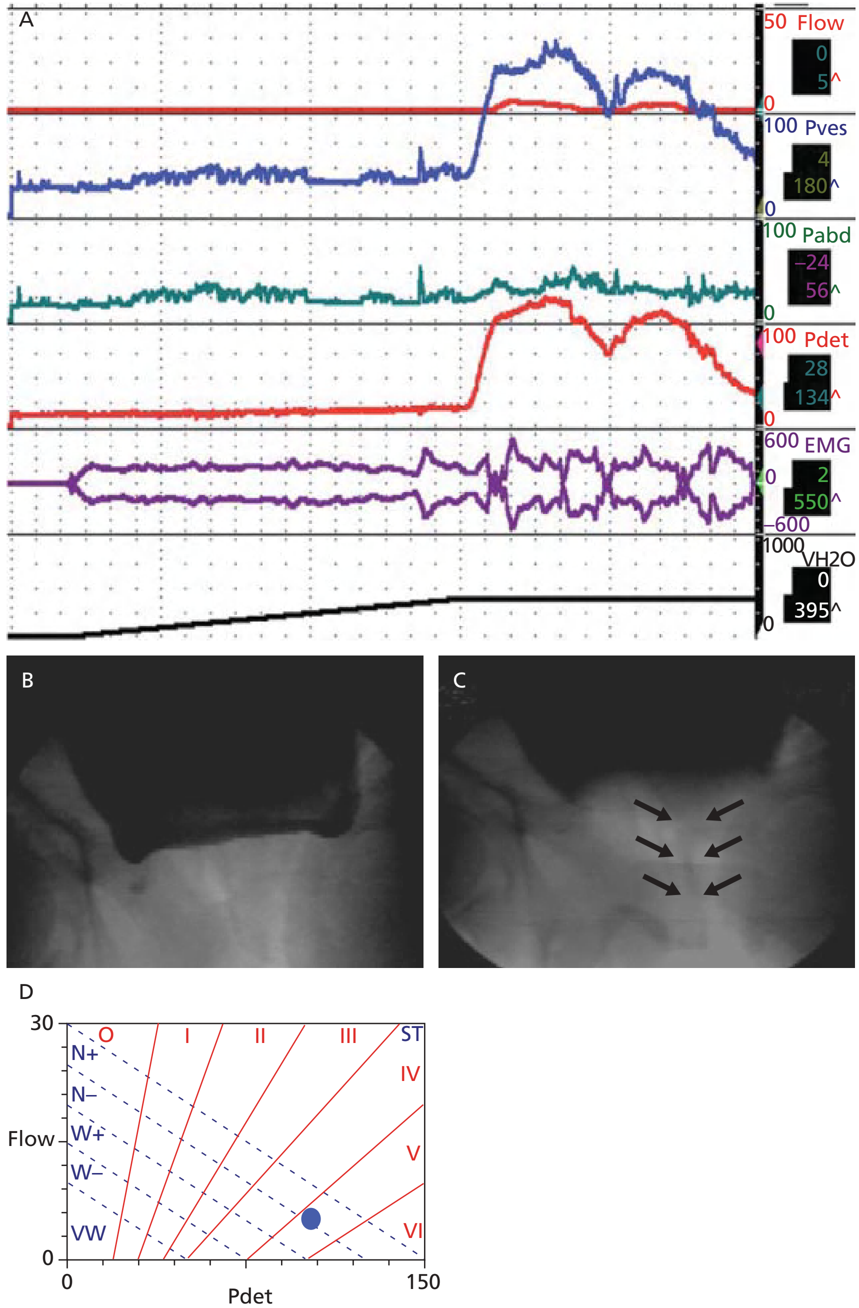

Figure 120.7 (A) Urodynamic tracing of a 63-year-old man with one episode of acute urinary retention on tamsulosin for 5 days. At a bladder volume of approximately 400 mL, the patient had a voluntary detrusor contraction. Maximum flow (Qmax) = 5 mL/s; detrusor pressure at maximum flow (Pdet@Qmax) = 117 cmH_2O (vertical line); maximum detrusor pressure (Pdetmax) = 123 cmH_2O; voided volume = 215 mL; postvoid residual volume (PVR) = 174 mL. (B) X-ray obtained just prior to voiding shows a flattened bladder base characteristic of benign prostatic obstruction. (C) X-ray obtained at Qmax (vertical line in A) reveals the prostatic urethra to be elongated and barely visible. (D) Detrusor pressure and uroflow plotted on the Schafer nomogram (grade 5 obstruction).

On fluoroscopy, the classic appearance of postradical prostatectomy stress incontinence is the funnel of bladder-urethral anastomosis at rest, with contrast seen in the bulbar or distal urethra during increases in abdominal pressure (Figure 120.8). The presence of and size of the urodynamic catheter used to measure leak point pressure may itself impact the recording and may mask sphincteric incontinence or suggest urethral obstruction when it is not clinically relevant.

In the majority of patients, the etiology of incontinence will be apparent after a careful history, physical examination, voiding diary, and pad test. However,

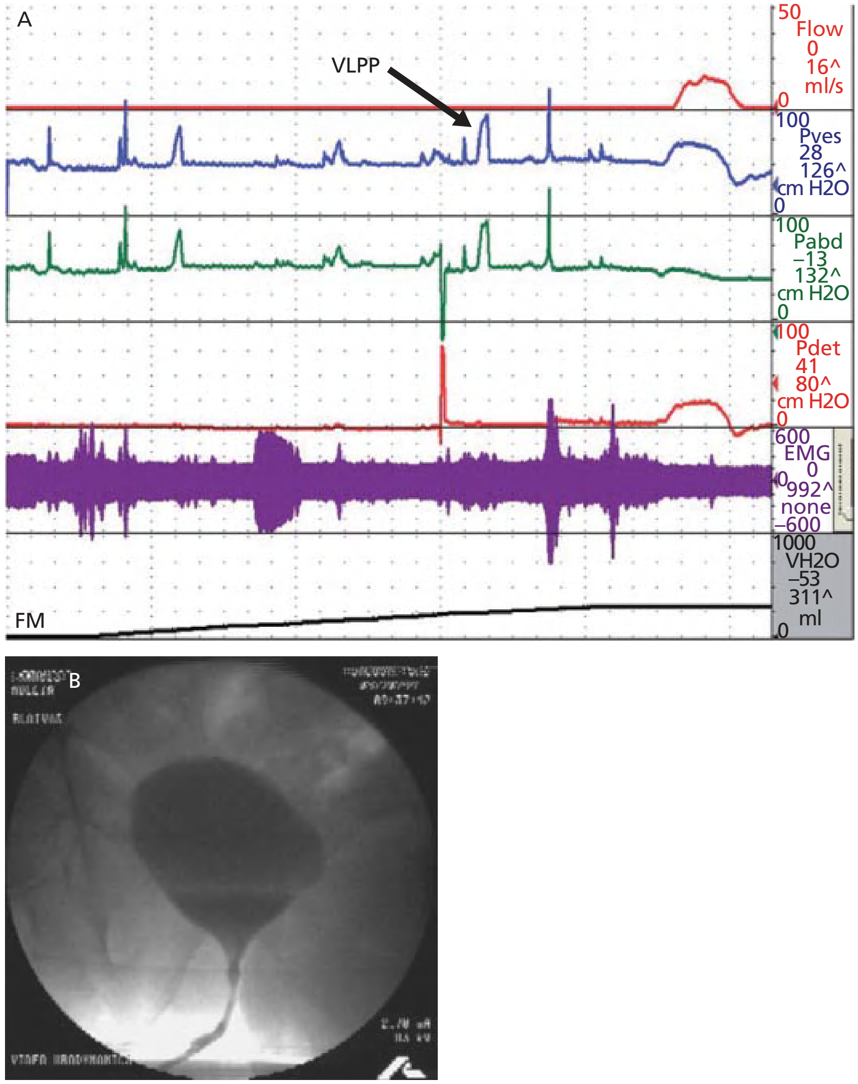

Figure 120.8 (A) Urodynamic tracing of a 72-year-old man 7 years post radical prostatectomy. His only prior treatment for incontinence was a collagen injection. He wears absorbent pads daily and he changes them three times per day. First sensation of filling (FSF) = 211 mL; first urge = 299 mL; severe urge = 305 mL; bladder capacity = 311 mL; Valsalva leak point pressure (VLPP) = 84 cmH_2O; maximum flow (Qmax) = 16 mL/s; detrusor pressure at maximum flow (pdet@Qmax) = 23 cmH_2O; maximum detrusor pressure (Pdetmax) = 23 cmH_2O; voided volume = 317 mL; postvoid residual volume (PVR) = 0 mL.
(B) X-ray obtained at VLPP shows contrast throughout the entire urethra.

detrusor overactivity and low bladder compliance can only be diagnosed with urodynamic studies.

Conclusions

Indications for urodynamics in men with LUTS depend upon the threshold of the clinician for obtaining the most accurate diagnostic information. The underlying pathophysiology of LUTS in men with BPH consists of urethral obstruction, impaired detrusor contractility, detrusor overactivity, and urgency. Accurate diagnoses can only be made with urodynamics, especially in cases where a surgical treatment is considered. Pressure–flow evaluation has been and remains the only "absolute way of diagnosing BOO" [1]. Although PFS has not been shown to predict responses to medical therapy, numerous studies have demonstrated that those patients with proven obstruction benefit more from prostatectomy than those who are not obstructed or have impaired detrusor contractility [9, 21]. Regardless, from a clinical viewpoint, videourodynamics serves no purpose unless the clinician bases their therapy on the results of the study, and urodynamics is only useful if detrusor overactivity and sensory urgency are treated differently from prostatic obstruction.

Notwithstanding these theoretic considerations, PFS is essential and videourodynamics preferable for men who have failed conservative and surgical therapies, particularly those considering more invasive treatment. Further, videourodynamics is recommended for men with known or suspected neurologic disease, including those with a history of spina bifida, diabetes mellitus, cerebral vascular accident, spinal cord injury, multiple sclerosis, Parkinson disease, and multisystem atrophy. Also, men with a history of major pelvic surgery or prior pelvic radiation and LUTS should undergo urodynamic evaluation.

Finally, even if videourodynamics were found to have no clinical import, it is still the best method of defining normal and abnormal physiology. Understanding physiology is the means by which new hypotheses are developed, leading to new research, new diagnostic methodologies, and, ultimately, new and more effective therapies.

CHAPTER 121

Office-Based Cystoscopy: Continued Advances

Judson D. Davies & Sam S. Chang
Department of Urologic Surgery, Vanderbilt University Medical Center, Nashville, TN, USA

Introduction

Cystourethroscopic examination of the bladder and urethra remains the gold standard for the diagnosis of lower urinary tract disorders. It offers direct visualization of the bladder urothelium and provides initial access to the ureteral orifices for assessment and treatment of the upper urinary tracts. It is a cornerstone in the evaluation of gross and microscopic hematuria, and is useful in the investigation of lower urinary tract symptoms. Instruments passed through the cystoscope or specially-designed resectoscopes allow minimally invasive diagnosis and treatment of identified pathology. This chapter summarizes the role of cystoscopy (both rigid and flexible) as well as recent innovations in office cystoscopy.

Cystourethroscopy is performed using either rigid or flexible endoscopes. Endoscopes are measured with the French scale and are available in sizes to accommodate both pediatric (8–12F) and adult patients (16–25F). The French scale is equal to the diameter of the cylinder in millimeters multiplied by three, not the circumference as is sometimes thought. Increasing French units correspond to larger diameter endoscopes.

Rigid cystoscopy

Rigid cystoscopes are multicomponent instruments that consist of a sheath, an obturator, a bridge, and a telescope (Figure 121.1). The sheath provides a connection to the irrigation system. An obturator is placed through the sheath that aids entry into the bladder through the urethra. Most are hinged to allow a better angled approach past the male bulbar and prostatic urethra. Once inside the bladder, the obturator can be exchanged for a telescope with a bridge that allows for the passage of a variety of treatment implements (i.e. wires, stents, ureteral catheters, laser fibers). The light source connects directly to the telescope, which uses fiberoptic illumination and a rod–lens imaging system to transmit the light and image to the eyepiece. Various lens angles enable the endoscopist to evaluate adequately the entire urethra and bladder. The 0° lens allows the best view of the urethra, providing a straight image. This degree lens is many times the most useful in patients with urethral stricture disease. A 30° lens is used to visualize the trigone, posterior wall of the bladder, as well as the lateral side walls. It is the most commonly used lens in rigid cystoscopy. A 70–90° lens is often used to assess the dome and anterior bladder neck.

Spring-loaded resectoscopes are typically used for the resection of bladder lesions and prostatic hyperplasia. These implements are best used in conjunction with a 30° lens–rod system and require the use of a large-bore sheath (24–26F). Continuous flow irrigation, which utilizes an outer sheath with both inflow and outflow ports, prevents the bladder from compressing on itself during the procedure. This allows the area of interest,

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

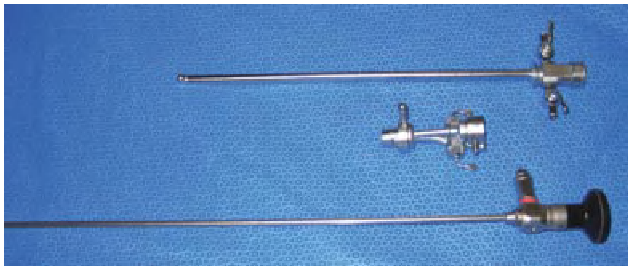

Figure 121.1 Basics of the rigid cystoscope (from top to bottom): metal sheath with inflow and outflow ports, bridge, and rod–lens system to which the light source it attached.

e.g. a bladder tumor, to remain fixed in space to facilitate resection. Continuous irrigation provides for more efficient resection and enhanced visualization, especially in the setting of transurethral resection of the prostate (TURP).

Rigid cystoscopes provide a relatively large working port to accommodate a variety of accessory instruments. This is a major advantage; however, the large size of the rigid cystoscope decreases its applicability in males unless general or regional anesthesia is utilized. Additionally, patients must be placed in the dorsal lithotomy position to facilitate an adequate examination. Rigid cystoscopy, therefore, is difficult to perform in the male patient outside of the modern operating room.

Procedures

Rigid cystoscopy is utilized to assess the bladder and upper urinary tracts for diagnostic evaluation of multiple clinical entities, such as hematuria, voiding complaints, and urothelial carcinoma. Retrograde imaging of the ureter and renal pelvis can be accomplished with the use of contrast injected through small catheters passed into the ureteral orifice under cystoscopic guidance. Ureteral stents are commonly inserted via the rigid cystoscope. Upper tract access for ureteroscopy may also be established with the use of wires and open-ended catheters. After wire passage has been confirmed with the use of fluoroscopy, the rigid cystoscope may be exchanged for a ureteroscope. Other uses are possible but have been largely supplanted with flexible cystoscopy.

Technique

After obtaining informed consent and verifying proper instrument sterilization and availability, the patient should be prepped and draped in a standard sterile fashion. In both male and female patients, lubricant jelly should be instilled into the urethra before the procedure. If the meatus or urethra is unable to comfortably accommodate the cystoscope, dilation should be performed. This can be accomplished with the use of urethral sounds in a serial fashion. The urethra should be dilated to a diameter of at least 2 French units greater than the instrument (e.g. dilate to 26F if utilizing a 24F cystoscope).

In the male, the penis should be grasped and straightened as the endoscope is introduced to allow for inspection of the fossa navicularis and the anterior urethra. As the scope traverses the anterior urethra, the examiner's hand should be depressed to bring the penis parallel with the floor. This allows for examination of the membranous urethra and prepares the examiner to view the prostatic urethra. The verumontanum is noted when the examiner reaches the prostatic urethra. The prostatic lobes are seen laterally at this point in the examination. When the bladder neck is in view, it is often necessary for the examiner to depress the endoscope by dropping their hand toward the floor so as to account for the gentle upward angulation encountered before entering the bladder [1].

Once the endoscope is inside the bladder, a systematic evaluation of the entire bladder surface is performed in a routine and reproducible fashion. The trigone is the first landmark encountered when visualizing the bladder with a 30° lens. The examiner should follow the trigone laterally to identify the ureteral orifices effluxing clear urine. Next, attention should turn towards examination of the bladder floor beyond the trigone and the posterior wall. The lateral walls are then carefully inspected by rotating the lens side to side. The dome and anterior bladder wall are best viewed with the 70° lens. The scope should be rotated 180° to facilitate this part of the procedure, paying close attention to keeping the camera head level (if one is being utilized). The air bubble serves as the landmark for the dome. It is often necessary to apply pressure just superior to the pubic bone when visualizing the anterior bladder neck.

Flexible cystoscopy

Flexible cystoscopy of the urinary tract is a fairly recent phenomenon. In 1973, Tsuchida and Sugawara reported utilizing a flexible "fibercystoscope" for examination of the bladder neck [2]. Since the development of the first purpose-built flexible cystoscope in 1984, flexible fiberoptic cystoscopy has become an accepted diagnostic and therapeutic modality, and today is the most commonly performed in-office procedure by the practicing urologist. The development of working ports, smaller cystoscope diameter with preserved image quality, active deflection, and most recently digital cystoscopes, have greatly enhanced the ability of the user to apply flexible cystoscopy for a variety of diagnostic and therapeutic applications. When compared to rigid cystos-

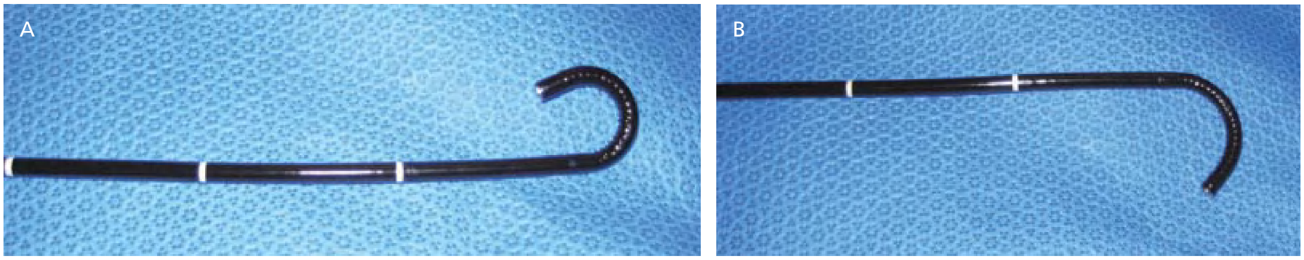

Figure 121.2 (A, B) Tip of the flexible endoscope can be deflected 180–220° to allow visualization at nearly any angle.

copy, flexible cystoscopy is more comfortable for patients and can be performed with only local anesthesia. The deflection capabilities of the flexible cystoscope allow for easier passage through the bladder neck, as well as superior visualization of the anterior bladder wall (Figure 121.2).

However, there are disadvantages to flexible cystoscopy. Flexible endoscopes are costly and require more delicate care when compared to rigid cystoscopes. These instruments have smaller irrigating ports and lack a separate working sheath. As a result, changing lenses, assessing residual urine and repeat evacuation of irrigant and/or urine cannot be completed without entirely removing the endoscope or actually withdrawing gradually contents via the single, small-caliber channel of the irrigation port.

Simply by its nature, the image obtained from a flexible fiberoptic cystoscope is inferior when compared to the rod–lens system employed in rigid cystoscopy. Fiberoptic technology has distinct imaging limitations owing to the finite diameter of the image-carrying glass fibers that make the pixelated "screen door" effect insurmountable [3]. There are generally three fiberoptic bundles within the shaft, two for light and one for the image. The image obtained by the fiberoptic bundle is a composite matrix of each individual fiber in that bundle, analogous to a newspaper photograph in which multiple dots merge into a single reconstructed image. Digital endoscopy, as discussed below, is able to overcome the limitations of fiberoptic endoscopy.

Procedures

The single most common indication for flexible cystoscopy is evaluation for hematuria, whether gross or microscopic. Visualization of the entire urethra and bladder can be accomplished efficiently and without significant discomfort. Other diagnostic applications include its use in the evaluation of male or female voiding dysfunction. Flexible cystoscopy, however, is not indicated in the routine evaluation of male voiding dysfunction thought to be attributed to outlet obstruction from benign prostatic hyperplasia (BPH), as the endoscopic appearance of the prostatic urethra and bladder does not predict the response to BPH therapy [4]. However, endoscopic assessment is appropriate and often necessary in men being considered for surgical therapy of outlet obstruction to rule out the presence of urethral stricture or bladder neck contracture, especially in those individuals who have undergone prior transurethral surgery. It is essential as well to evaluate any suspected anatomic abnormalities.

In addition to diagnostics, there are many therapeutic office-based applications. These include the injection of urethral bulking agents for stress urinary incontinence and intravesical injection of botulinum toxin for voiding dysfunction. Removal of ureteral stents or of foreign bodies is another commonly employed procedure that is made safe, efficient, and reliable with the use of modern flexible cystoscopy. This can be done with grasping forceps, a retractable lasso device, or four-pronged grasping forceps with a retractable sheath. Once the cystoscope is introduced into the bladder and the object is identified, the grasping device is passed down the working channel and into the field of view. The object is then firmly grasped and the endoscope and graspers are removed as a unit under direct visualization.

Suspicious lesions in the bladder may be sampled in the office setting with the use of flexible biopsy forceps and electrocautery. When biopsies are to be obtained, a topical anesthetic agent (lidocaine 1% solution) is instilled into the bladder and left in place for 10 min prior to the procedure. An electrocautery unit and probe must be readily available in this situation. A nonconductive solution such as water or glycine must be the irrigant when electrocautery is used. Laser fulguration of small lesions is possible and is becoming increasingly used. This option is especially useful in patients with known rapidly recurring, low-grade, papillary tumors of the lower urinary tract.

Technique

The patient should be prepared in a fashion analogous to that for rigid cystoscopy. In both male and female patients, lubricant–anesthetic gel should be instilled into the urethra before the procedure. A recent

meta-analysis has demonstrated that subjects who received anesthetic-impregnated gel were 1.7 times more likely not to experience moderate-to-severe pain than subjects who had no intraurethral anesthetic instillation [5].

Examination of the urethra and bladder with the flexible cystoscope is performed in a slightly different manner from rigid cystoscopy. The anterior urethra can be viewed in a retrograde manner. The prostatic urethra should not be examined during retrograde passage of the endoscope as it will often appear obstructed. Instead, the prostatic urethra should be examined antegrade as the endoscope is being withdrawn from the bladder [6].

As with rigid cystoscopy, the bladder should be examined in a predetermined systematic fashion that the examiner can reliably duplicate to ensure adequate examination of its full contour. A standardized approach also aids in reliable documentation. The bladder should be cleared of turbid urine, clot, and debris prior to examination. The bladder is then filled with a sufficient volume to allow distention of mucosal folds. The bladder does not have to be distended as much as in rigid cystoscopy for adequate visibility. The first landmark in the bladder that is often seen is the air bubble at the dome. One systematic approach then is to evaluate the bladder by starting along the 12 o'clock position by pulling the endoscope toward the bladder neck and along the midline until the bladder neck is just entered. The endoscope is then returned to the dome and rotated from the 12 to the 4 o'clock position, and then from the 12 to the 8 o'clock position in a counter-clockwise fashion. Next the scope is returned to a neutral position. The scope is then deflected to the six o'clock position to view the trigone. The 5, 6, and 7 o'clock positions are examined as previously described.

Advances in office cystoscopy

The use of video cameras in endoscopy was introduced in 1956 by French researchers [3]. This development enhanced ergonomics, safety, and success rate for pathologic findings. This approach has many advantages, including the avoidance of contact with body fluids, patient education, and documentation through the use of digital camera technology [1].

Videoendoscopy with flexible scopes allows patients to visualize normal and abnormal anatomy, and thus helps them to understand their pathology. In male patients, videocystoscopy utilizing a monitor has been shown to produce a 40% decrease in the pain and discomfort level compared to those who did not view the procedure on the monitor [7].

Recently, the key advance in office cystoscopy has been the continued improvement and innovation in the visualization mechanism. Digital (distal sensor) endoscopy based on CCD (charge-coupled device) and CMOS (complementary metal oxide semi-conductor) chips has recently been introduced into the field of endourology. Digital sensors are composed of millions of photodiodes which convert photons into electric current that is later transformed into voltage, amplified, and converted to a digital form [3]. On both types of chips, the information is transferred to a controller box for image presentation or storage (i.e. the box that is connected to the cystoscope).

Distal sensor cystoscopes based on these technologies were introduced in an effort to provide urologists with better optical resolution, contrast, color differentiation, and improved durability. Digital image capturing allows for plug-and-play capability. Contemporary digital sensor endoscopes are able to meet the size requirements of flexible cystoscopy. They are already superior to flexible fiberoptic endoscopes in terms of weight and are thus easier to handle during procedures. Additionally, distal sensor cystoscopes do not require white balancing and camera focusing. *In vitro* evaluation has demonstrated that distal sensor cystoscopes are superior to fiberoptic cystoscopes in terms of resolution, contrast discrimination, and red color differentiation [8].

The first commercial digital flexible endoscope was the ACMI DCN-2010 introduced in 2005 (ACMI, Southborough, MA, USA). Quayle *et al.* compared this cystoscope with three contemporary fiberoptic scopes and found the digital scope to provide superior optics [9]. Okhunov *et al.* conducted a prospective clinical comparison of distal sensor (digital) and fiberoptic cystoscopes in over 1000 patients who underwent office-based cystoscopy. All surgeons found the digital sensor endoscopes to be lighter and easier to handle. Both subjective optical and functional metrics were significantly better with the distal sensor cystoscopes. Substantial differences were found with cystoscope deflection when instruments were placed in the working channel; however, the evaluating surgeons did not believe that this diminished function. Finally, both the fiberoptic and digital cystoscopes proved durable with a 0.2% repair rate during the study period [10]. It remains to be seen if distal sensor technology will ultimately prove cost-effective.

Another technology that might prove useful in office-based cystoscopy is narrow-band imaging (NBI), which is made possible by the CCD chips. This narrrow bandwidth of light (415 and 540 nm) is strongly absorbed by hemoglobin and penetrates only the surface of tissue. By narrowing the bandwidth of light from the flexible cystoscope, NBI improves the definition of the epithelial surface and emphasizes the mucosal microvessels. NBI has demonstrated superior sensitivity for identifying recurrent flat and papillary superficial bladder tumors in a surveillance setting when compared with standard

white light cystoscopy. This technology was not studied for the more difficult to detect lesions, such as carcinoma *in situ* [11].

Conclusions

As technology continues to evolve, office-based cystoscopic procedures continue to improve and expand. The ability to utilize flexible cystoscopy in an increasing number of clinical situations has benefitted both physicians and patients. At the same time, it continues to be the standard diagnostic evaluation tool for the practicing physician.

CHAPTER 122

Equipment Set-up and Patient Handouts

Mayank Mohan Agarwal,[1,2] Crystal R. Combs[1] & Gopal H. Badlani[1]

[1]Wake Forest University Baptist Medical Center, Winston Salem, NC, USA

[2]Postgraduate Institute of Medical Education and Research, Chandigarh, India

Introduction

Team collaboration and communication are essential to successful endourologic procedures. The entire staff must be thoroughly familiar with the equipment and instrumentation needed for specific procedures; they must ensure that instruments are functioning properly to avoid delays, and that the operating room (OR) set-up meets the surgeon's specifications. In this chapter, we describe the responsibilities of the urology nursing team for setting up the equipment, instrumentation, and supplies, and for organizing the OR for lower urinary tract endoscopy and vaginal surgery.

Operating room set-up

The necessary equipment should be assembled in the OR suite and its function assessed before the patient enters. The OR set-up should accommodate at least one (preferably two) table set-ups, the OR table, endoscopic video cart (Figure 122.1), anesthesia equipment, laser unit, electrosurgical unit, computer station, and, preferably, C-arm fluoroscopy. Space for the latter is preferable since the same room will usually also be used for various fluoroscopic procedures (e.g. ureteral stenting, ureteroscopy, percutaneous renal interventions). In addition, there must be adequate room to set up equipment, move about freely, assist the anesthesiologist, and perform documentation. There must be ready access to the two-way telephone.
